cent, responsible for secondary cases (table 1). The rate was highest for patients less than 1 year of age, although their number is scarcely within significant limits. The infecting case rate is definitely high for children of 1 to 4 years (5.4 per cent), with 580 cases represented. The frequency continues relatively great among older children, but the age group representing young adolescent patients evidences a marked decline. Of 213 patients aged 15 to 19 years, none were proved responsible for other cases of scarlet fever.

TABLE 1.—*Infecting Cases According to Age Groups*

Age Group	Number of Cases	Infecting Cases	
		Number	Per Cent
Under 1 year	22	2	9.1
1 to 4 years	580	31	5.4
5 to 9 years	1,197	58	4.8
10 to 14 years	445	19	4.3
15 to 19 years	213	0	0.0
20 years and over	583	4	0.7
Total	3,040	114	3.7

An appreciable proportion (4.7 per cent) of patients under 15 years of age infected one or more of their contacts after release. Those over 15 years of age were responsible for relatively few secondary cases. The convalescent carrier state has been demonstrated bacteriologically to be less prolonged with adults than with children. It is also probable that the child returns to a relatively more susceptible group than do adults. An active factor in extending communicability is the presence of complications during convalescence. These conditions develop in children much more frequently than in adults.

Distinction might well be made between children with scarlet fever and adults with the disease, in respect to required isolation. Equally prolonged isolation appears illogical. The data suggest a required minimum of not more than three weeks. The practicability of a two week interval should be determined. A significant saving in hospital days would be effected for patients thus isolated. The individual's absence from employment would be less, and the advantage to those responsible for care and support of families, material.

No significant difference between the sexes was determined in respect to the likelihood of transmitting the disease.

FREQUENCY OF INFECTING CASES AMONG PATIENTS WITH SIMPLE AND WITH COMPLICATED SCARLET FEVER

Scarlet fever differs from most other communicable diseases in that complications are apparently due to the same infectious agent responsible for the acute stage of the disease. A patient released at the end of twenty-eight days without suppurative complications of the nose, throat or ears should therefore be less a menace to others than the patient in whom complications develop. Hemolytic streptococci have been found to disappear from the nose and throat much more rapidly when secondary pyogenic conditions are absent. Infecting cases are relatively few among simple cases. The number is more than twice as great when one of the three common complications, rhinitis and sinusitis, cervical lymphadenitis or suppurative otitis media, has developed during convalescence.

TABLE 2.—*Frequency of Infecting Cases Among Patients with Simple and with Complicated Cases of Scarlet Fever*

	Number of Cases	Infecting Cases	
		Number	Per Cent
Simple	1,904	45	2.4
Complicated	1,136	69	6.0
Total	3,040	114	3.7

BACTERIOLOGIC CONTROL OF SCARLET FEVER CONVALE NTS

The commonest control sures for scarlet fever demand a minimum isol period expressed in days' time from onset or d report, with provision for extension if complica occur. The effectiveness of this procedure was ed for one year as a control observation, the g being the usual one of infecting cases. Pati th an uncomplicated course were released at th of twenty-eight days. If complications d , with clinical recovery before the end of this per, the patients were likewise released at that time. When complications persisted, restriction was continued until clinical recovery; or until the fifty-sixth day, when the patient was released, irrespective of his condition.

Another year, patients without complications were released after twenty-eight days, but cultures for hemolytic streptococci were taken from the nose and throat on the twenty-fourth and twenty-fifth days. The presence or absence of streptococci was tabulated in relation to the number of patients who thereafte caused scarlet fever among familial contacts. Releas was permitted irrespective of culture report.

TABLE 3.—*Infecting Cases in Relation to Cultures for Hemolytic Streptococcus Taken at Time of Release*

	Culture	Number of Cases	Infecting Cases	
			Number	Per Cent
Simple	+	174	3	1.6
	0	1,638	40	2.4
Complicated	+	92	11	11.9
	0	1,011	56	5.5

In the event of complications, isolation was termi nated when two successive cultures from the nose, throa or other affected part were free from hemolytic strep tococci, and under certain circumstances at the end o fifty-six days. Continued isolation for complicate cases was thus placed on a bacteriologic rather than clinical basis, since the patient was released when th cultures became negative, irrespective of the clinica condition.

The relative value of bacteriologic control in simpl and in complicated cases is shown in table 3.

Relatively few patients with uncomplicated scarl fever (174 of 1,812) continued to have hemolyt streptococci in the nose and throat when released fro isolation on the twenty-eighth day of the disease.

The gross infecting case rate was 2.4 per cent. Th rate was essentially the same for the group who we carriers of hemolytic streptococci as for those wh were not. Present bacteriologic methods offer improvement over clinical methods in the control uncomplicated cases isolated for twenty-eight day However, the possibility exists that patients witho complications may be released at an earlier date wi safety. Serial culture studies during convalescence weekly intervals might justify a trial of a three week isolation program. An important reservation shou be made; namely, that absence of complications, pa ticularly of the nose, must be accurately determined by a physician experienced in scarlet fever.

By contrast, an essential difference was demonstrated for complicated cases, depending on whether hemolytic streptococci were present or absent when the patient was released. The infecting case rate was 11.9 per cent for ninety-two patients who still harbored hemolytic streptococci. The rate was 5.5 per cent for 1,011 patients whose release cultures were free from hemolytic streptococci. A definite measure of safety is provided when complicated cases are released by bacteriologic control. However, two successive negative streptococcus cultures do not provide a measure of control comparable with that of simple cases. Increased efficiency might be conferred through requirement of three negative cultures instead of two. Certain complications may be more satisfactorily controlled by a bacteriologic method, because proper specimens are more readily obtained.

RELATIVE IMPORTANCE OF THE SEVERAL COMPLICATIONS IN PROLONGING COMMUNICABILITY

Complications are not all of equal importance in prolonging communicability. A series of 1,136 patients having a complicated course was divided into four groups. The first group had, as the only complication, rhinitis and sinusitis; the second group, suppurative otitis media; and the third, cervical lymphadenitis. The last complication is of importance because of the usual relationship to prolonged or secondary infection of the throat. The fourth group included patients having more than one complication, largely combinations of the preceding three. The infecting case rates for these four groups are presented in table 4.

TABLE 4.—*Infecting Cases by Type of Complication*

Complication	Number of Cases	Infecting Cases	
		Number	Per Cent
Otitis media, suppurative..........	145	4	2.8
[illegible]	260	16	6.2
[illegible]	437	28	6.4
[illegible]	294	21	7.1
Total........................	1,136	69	6.0

The infecting case rate for patients having had rhinitis and sinusitis is greater than for any other group with a single complication. It is the largest group. Although representing only 14 per cent of all cases, it was responsible for 40 per cent of infecting cases. Cervical lymphadenitis ranks a close second; but, surprisingly, the patient with suppurative otitis media is scarcely more infectious than is the patient released after simple scarlet fever.

Rhinitis and Sinusitis.—Since patients with scarlet fever complicated by rhinitis are responsible for more secondary cases than any other group, a more intimate analysis of this particular complication was made.

This complication by no means constitutes an entity. One large division includes patients with nasal discharge associated with primary involvement of the sinuses. A second group includes patients in whom there developed a rhinitis corresponding to a coryza of the common cold type. Hemolytic streptococci were almost invariably associated with the first group, uncommonly with the second. The two are sufficiently distinct clinically and pathologically to suggest significant differences in ability to transmit the disease after release from isolation.

TABLE 5.—*Clinical Forms of Rhinitis Observed During Scarlet Fever Convalescence*

Type of Nasal Condition on Release	Number of Cases	Infecting Cases	
		Number	Per Cent
1. [illegible]	116	17	14.7
[illegible]	149	13	8.7
[illegible]	261	13	5.0
[illegible]	97	3	3.0
2. [illegible]	398	10	2.5

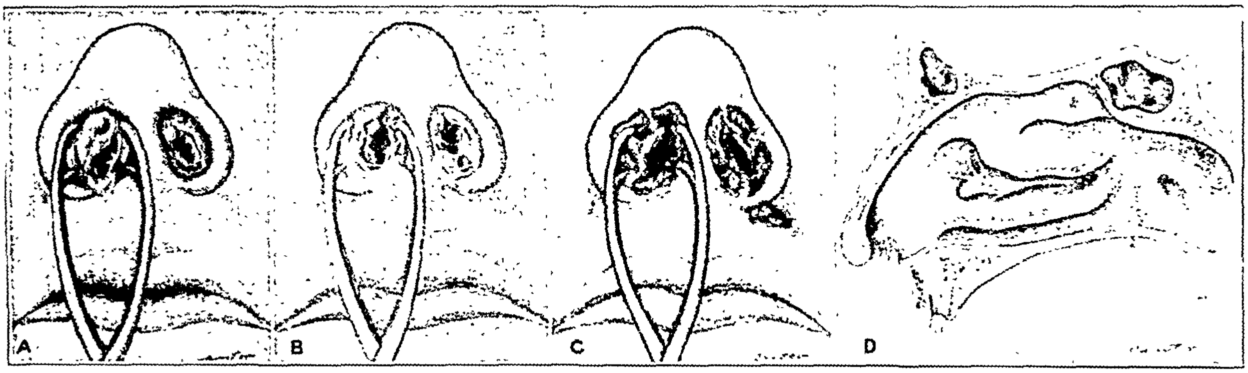

Fig. 1.—Rhinitis and sinusitis of scarlet fever convalescence: *A*, active purulent discharge; *B*, seropurulent discharge; *C*, crusting of internal and external nares; *D*, mucopus on turbinates, no discharge.

Infecting cases occurred in greater number among patients having rhinitis of the type first described than in any other group of scarlet fever convalescents of this series. The condition may be termed rhinitis and sinusitis of scarlet fever convalescence. Four clinical subdivisions were made, dependent on the duration of the process (fig. 1).

Rather striking differences exist, in respect to secondary cases, depending on the particular stage of the process at the time of release. The active condition (fig. 1 *A*) represents a high degree of communicability; the last stage (fig. 1 *D*) is scarcely more important than the simple uncomplicated case.

Bacteriologic examination of the secretion for hemolytic streptococci serves to corroborate clinical judgment in differential diagnosis. Patients of type 1 can be released with safety only after clinical recovery or after freedom from discharge and from hemolytic streptococci in cultures. The bacteriologic method alone is not adequate. Even with two negative cultures, infecting cases were frequent.

The most common form of nasal disorder was clinically a coryza of the common cold variety, type 2 (fig. 2), showing a thin serous discharge of relatively short duration. Often entire hospital wards are involved, evidently representing transmission of a secondary virus. Cultures from the secretion were usually free from hemolytic streptococci. Cases presenting this complication represented 40 per cent of all nasal conditions, and yet the infecting case rate was only 2.5 per cent, essentially the same as that observed for patients with no abnormal condition of the nasal passages (2.4 per cent). Prolonged isolation because of this complication appears unjustified.

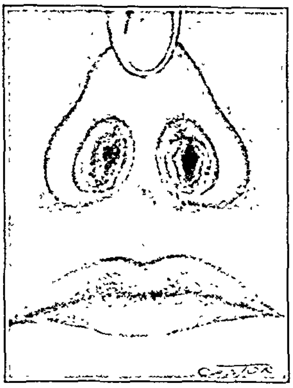

Fig. 2.—Coryza of common cold type in scarlet fever convalescence.

Suppurative Otitis Media.—Patients having purulent discharge from the ears in no way approach in importance those with similar involvement of the nasal passages (table 4). Only 4 among 145 cases became infecting cases (2.8 per cent). Most of the group were released with discharge from the ear still present, but free from hemolytic streptococci. Only one caused another case of scarlet fever. When hemolytic streptococci were demonstrable, the infecting case rate was as high as that for patients with rhinitis. Long continued isolation of patients bacteriologically free from hemolytic streptococci appears unnecessary.

Cervical Lymphadenitis.—The causal relationship between secondary angina and enlarged cervical lymph nodes is not fully appreciated. Hemolytic streptococci usually remain on the mucous surfaces of the pharynx. The infecting case rate is high. A measurable degree of safety is conferred by assurance that patients with this complication are free from hemolytic streptococci before they are released.

Table 6.—*Relative Importance of Clinical Discharge and Presence of Hemolytic Streptococci at Release*

Complication	Purulent Discharge	Hemolytic Streptococci	Number of Cases	Infecting Cases Number	Infecting Cases Per Cent
Rhinitis	+	+	20	1	5.0
	+	0	204	17	8.3
	0	+	4	1	25.0
	0	0	203	8	3.9
Otitis media	+	+	18	1	5.5
	+	0	68	1	1.5
	0	+	2	0	0.0
	0	0	50	1	2.0
Cervical adenitis	+	+	0	0	0.0
	+	0	12	3	25.0
	0	+	16	2	12.5
	0	0	225	11	4.9
Multiple complications	+	+	25	5	20.0
	+	0	150	14	9.3
	0	+	5	1	20.0
	0	0	101	1	1.0

Multiple Complications.—In a single patient, more than one of the conditions mentioned, or indeed all three of them, may develop during convalescence. Under such conditions the carrier rate is much increased, particularly if rhinitis and sinusitis are represented. The infecting case rate is high.

The relationship between clinical and bacteriologic control methods is shown in table 6.

SEASONAL PREVALENCE OF INFECTING CASES

Physicians experienced in the clinical management of scarlet fever readily appreciate the seasonal variation of complications during winter and spring months. Complications have been emphasized as the dominant factor in infecting cases. The suggested variation in infecting cases was corroborated by figure 3.

The first six months of the year showed a rate well above the annual average. The greatest frequency occurred during March and May, and the rate dropped to a low level during July to September. When a curve of complicated cases was plotted by months, it was found largely to coincide with the distribution described. The presence of complications is not the only factor in this seasonal variation, because the rate for uncomplicated cases follows the same trend.

COMMENT

The efficiency of two methods for release of patients after scarlet fever has been studied. One method represented accepted practice—an isolation period of twenty-eight days for uncomplicated cases and release of patients with complicated cases thereafter on clinical recovery, with a maximum restriction of fifty-six days. The second method included the same minimum requirements for uncomplicated cases, but patients with complications were released when two successive cultures from the affected part were found free from streptococci. The infecting case rate was essentially the same under the two conditions.

The bacteriologic control possessed the advantage of prescribing an isolation better suited to the requirements of each individual patient. This method materially reduced the average period of isolation. The gain was entirely in the group having complications, patients ordinarily hospitalized for the longest periods. Simple uncomplicated cases, because of present legal requirements, showed no variation.

The patient with complications is responsible for most secondary cases. Attempted control by cultures for hemolytic streptococci gave results in no way comparable to the rate established by simple infections. The method possesses the value of generally decreasing the required period of isolation. The number of hospital days was appreciably less when patients were so released, and the results were essentially as good from the standpoint of infecting cases.

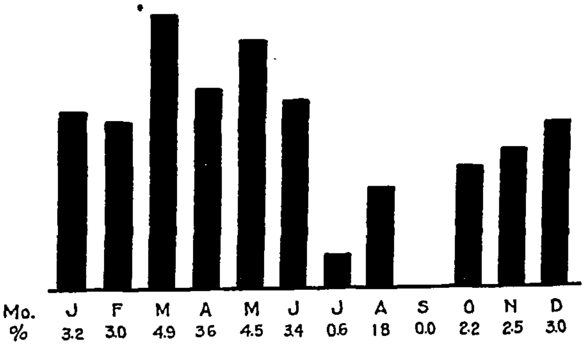

Fig. 3.—Seasonal variation in percentage of infecting cases; 1930 series, 1,948 cases; total infecting rate, 3.3 per cent.

An appreciable gain was thus made in respect to time lost from employment or from school. Patients with certain complications were safely released before complete recovery. From a clinical standpoint, this is no small consideration. Chronic suppurative conditions are more likely to progress favorably with outdoor exercise and lessened restriction of activity.

Epidemiologic data of particular value have been made available as a result of release on a bacteriologic basis. The general reliability of the method varies with the kind of case and the kind of complication. No advantage seemingly results from requiring negative cultures of simple cases at the end of twenty-eight days. The infecting case rate was not greater for those proved carriers than for patients free from the infectious agent. The outstanding position of the complicated case as the chief problem in the control of scarlet fever has been demonstrated. Certain complications are more likely than others to disseminate the infection. In order, rhinitis and sinusitis rank first, followed by secondary throat infections and suppurative otitis media. The latter complication under bacteriologic control is no more a source of danger than the simple uncomplicated case, and patients may be safely released before clinical recovery. Clinical classification has demonstrated that certain forms of rhinitis are without particular hazard; others are extremely likely to result in secondary cases.

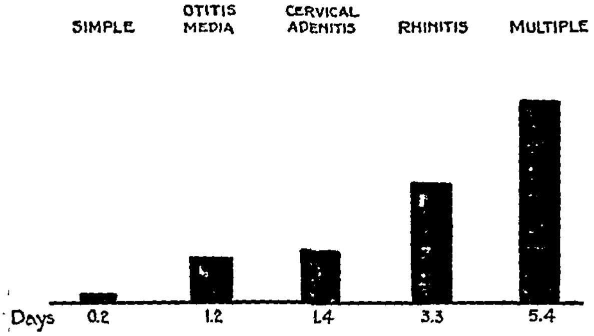

Fig. 4.—Comparison of clinical and time vs. clinical and bacteriologic methods of control (1927-1929). The average saving in hospital days per patient by complication is shown. The incidence of infecting cases was approximately the same for the two years.

Evidence has accumulated to show that patients of the older age groups could very safely have been dismissed at an earlier period. During certain times of the year the secondary case rate was materially lower. The practicability of shorter periods of isolation during late spring and summer should be further investigated.

CONCLUSIONS

This study indicates the existence of significant clinical differences among patients, permitting practical modification of isolation. This approach to the problem is suggested by the precept of individual consideration, from the acute stage through convalescence to release. The evaluation of communicability by clinical methods, including laboratory procedures, gives promise of more adequate and more equalized control.

Herman Kiefer Hospital.

ABSTRACT OF DISCUSSION

Dr. Milton J. Rosenau, Boston: I think that scarlet fever is a beautiful example to release one from the unfortunate situation in which one sometimes falls by drifting along the easier methods. Here is a disease that varies in time, in place and in accordance with the age and many other factors. If that is so, if the disease varies with the latitude, with the seasons of the year, in different age groups, and so on, why should not the quarantine restrictions, the isolation, the release and all the other public health measures adapt themselves to these variable factors which are known? There is no reason why the health officer in Florida or Alabama should apply the same restrictions to the control of scarlet fever in those localities as are applied in Connecticut, in Massachusetts, or in Michigan, where Dr. Gordon works. The same is true of summer and winter. We have little fear and there is little danger of scarlet fever spreading in the warm weather; why, then, could not the restrictions be relieved for six, seven or more months during the year, much to the advantage of the health officer, and so on? The same thing is true for the age group that we have seen. There is the difference in susceptibility, in the danger of spread, and in the menace of this infection in the different age groups. *Therefore, not only by individualizing but by applying the* knowledge we have of this disease and other diseases, with more precision in our public health administration based on a sound knowledge of epidemiology gained from facts such as we have just heard, I think that we shall be able to make progress along sound lines. I am favorably impressed with the yardstick that Dr. Gordon has used; that is, not taking the number of returned cases as a measure of the accuracy of the processes used, but the infecting cases, for, after all, infection is the important thing to consider in the control of this and any other disease.

Dr. Edward S. Godfrey, Jr., Albany, N. Y.: The same thought came to me that came to Dr. Rosenau, of the difficulties of investigating a disease such as scarlet fever, in which there are legal restrictions on the period of isolation that make it practically impossible for any one to determine the minimum period at which it is safe to release a patient. One must keep one's patients isolated for a certain period and is therefore unable to test the effect of a shorter period. It is a good thing that we have varying periods of quarantine in different parts of the country; to that extent at least we can see whether or not there is any substantial benefit from the longer periods. I agree that the infecting case rate is the proper rate to determine the efficacy of the release methods, provided due consideration is given to the composition of the family to which the child returns. It is obvious that if a child goes back to a family in which there are no children there are not likely to be any return cases. If an adult is attacked, it is usually after the children have been infected, and he returns to a home in which all are immune. In his chart on multiple complications, Dr. Gordon did not specify how many patients had rhinitis as one of the complications. It seems to me that a patient with nasal discharge is much more liable, even than the chart shows, to transmit the disease than one with throat or ear discharge, for the former patient gets the fingers soiled with nasal discharge. I think that Dr. Gordon ought to specify in his table the frequency of infecting cases among those having rhinitis as one of the multiple complications, as compared with those not having it. I have frequently observed that patients released from the hospital without discharge and discovered later to have caused return cases will be found, on careful inquiry, to have had a return of discharge after their release from the hospital or from quarantine. I should like to know whether that has been observed by Dr. Gordon in his cases. Finally, I think that we all ought to observe our cases more carefully and to collect figures, as Dr. Gordon has done, so that we may arrive at something like a scientific control of scarlet fever.

Dr. A. Clement Silverman, Syracuse, N. Y.: I agree with Dr. Gordon on the influence of season on scarlatinal complications and on the incidence of infecting cases. I find it much easier in the summer months to release my patients at the end of thirty days, which is the minimum legal isolation period. At other times I find that I often have to keep them six and seven weeks because of the appearance of the mucous membranes. I have found it much less easy to differentiate between simple coryza and sinusitis. For nearly two years my associates and I have been carrying on a study in which practically every one of our pediatric patients in the scarlet fever service has had the paranasal sinuses roentgenographed. Of 159 patients roentgenographed up to April, 1931, only 8 showed normal paranasal sinuses. Frequently, to be sure, the children showing dulness or haziness in their roentgenograms do not give any evidence of nasal discharge but show increased redness of the nasal mucous membranes, and many are entirely negative clinically. So far, we have not had an opportunity to study a control group of children in our locality who did not have scarlet fever. In the beginning of this study, it was hoped that the roentgenographing of sinuses might give us an opportunity to pick out those liable to become infecting cases; this evidently does not appear to be working out, although in one instance in which the mucous membranes looked normal clinically and the roentgenogram showed marked clouding of one antrum, the child apparently gave rise to a "return" case. It is perhaps worth emphasizing that a scarlet fever case may properly be counted as a return case only if it occurs from three to ten days following the arrival in the home of a patient discharged from the hospital. Nevertheless, it is often found that when the disease is very prevalent a great deal of opportunity for independent exposure may be present in the neighborhood and wrongly charged to the child returned home from the hospital. It would be interesting to have the age distribution in the return cases. I wondered whether the high percentage of infecting cases in the first year might not be due to the close association of mother and baby, if the mother is the person who is most commonly infected. It is obvious, of course, that the number reported in this age group is too small for significant percentage computation.

Dr. P. F. Lucchesi, *Philadelphia:* In reference to infectiousness, was desquamation considered in these cases? Were the cases of reinfection considered in this group and how long after the reinfection did you quarantine the patients?

Dr. J. E. Gordon, Detroit: Actual alteration of isolation under field conditions has been practiced in Detroit on the basis of differences among age groups. Adult patients are released after three weeks, and children after four. The frequency of infecting cases has been no greater than when all patients were released after isolation for four weeks. Investigations directed toward determining minimal isolation and quarantine requirements for scarlet fever are being conducted under the auspices of the Committee on Administrative Practice of the American Public Health Association. Information regarding unusual kinds of regulations is desired. We are particularly interested in unusual outbreaks of scarlet fever. Isolation and quarantine in significant geographic parts of the United States are being studied, that a general idea of the requirements for this disease may be determined. The age of contacts has been correlated with the number of secondary cases. The number of contacts probably immune has been determined by a history of previous scarlet fever and by Dick tests. Rhinitis was by far the most common element among patients having multiple complications. Exact data have been obtained of all combinations comprising this group included under multiple complications. I like Dr. Godfrey's statement in relation to the importance of rhinitis as an agent in transmitting scarlet fever. Clinically distinct differences among patients with rhinitis have been determined in relation to the likelihood of transmitting the disease. The two forms of rhinitis were distinguished on the basis of clinical studies and by bacteriologic methods. The coryzal form is regularly free from hemolytic streptococci and exhibited a distinct tendency epidemiologically toward ward and familial outbreaks. Desquamation has not been considered a pertinent factor in communicability.

Disease States Can Never Be Identical.—Just as no two human beings are precisely alike, not even twins from the same ovum, so two disease states can never be identical, even though they are produced by almost indistinguishable agents. Similarities do exist between disease states as well as between human beings. This is most noticeable in twins, quite common in families, not rare in communities, unusual between nations and most divergent in different races. A single anatomical feature, too, a peculiar mode of thought, a simple physiological process or an isolated pathological lesion may seem to be exactly the same in two different individuals; but each complete personality, each state of disease, is unique. When disease is regarded from this point of view, the slightest departure from the wholeness of health may produce a profound and lasting effect; for the significance of the injury may depend, not so much on its physical result, as on the interpretation that the patient gives it. —Longcope, W. T.: Methods and Medicine, *Bull. Johns Hopkins Hosp.* **50**:4 (Jan.) 1932.

SENSITIZATION DERMATOSES OF NONFUNGOUS NATURE

FOLLOWING SUPERFICIAL FUNGOUS INFECTIONS ("RINGWORM") OF THE EXTREMITIES *

CLEVELAND WHITE, M.D.
AND
SAMUEL J. TAUB, M.D.
CHICAGO

The recent original observations and investigations of Williams[1] in demonstrating that certain eruptions on the hands were a mycotoxic manifestation of distant active fungous foci has illuminated the mechanism of many heretofore etiologic puzzles. Williams called them dermatophytids, and numerous other subsequent publications have amply confirmed his original observations. One of us (C. W.) has recently observed a series of cases (eighteen) in which it appeared that an eruption of the glabrous skin of the body occurring either immediately or a short time after a flare up of fungous infection may occasionally be due to sensitization to substances other than circulating fungi or fungous toxins; the skin had apparently been rendered sensitive by the superficial fungous infection.

Williams was the first to advance the theory that hand lesions resulted from dissemination of fungi or their products from foci on the feet. Further investigations by Walthard,[2] Jadassohn[3] and Peck[4] have shown that (*a*) systematic cultures from the feet and hands were generally positive only from the feet; (*b*) the lesions on the hands generally appeared subsequent to those on the feet and sometimes followed irritation of the foci on the feet, and (*c*) the skin of patients with lesions of the feet and hands was practically always hypersensitive to intradermal injections of trichophytin. Sulzberger[5] felt after much observation and work that the probable mechanism, at least in a great many cases, was as follows: The fungi coming from the feet circulate in the blood and arrive in the allergic skin of the hands. Having arrived there, they are rapidly destroyed. It is for this reason that even after repeated careful searching, with the best possible technic, in almost all cases it is still impossible to find fungi in the hand lesions.

Although it has been demonstrated that superficial invading fungi can actually invade a lymph node and be grown in culture,[6] still one of us (C. W.) has never grown a positive blood culture for fungi after many attempts in some sixty cases. Peck was able to procure a positive blood culture in one case.

Infection of this nature on the hands has been classified into three groups:[7] (*a*) secondary to foot foci as originally described by Williams, (*b*) definitely

infected ones from fungi, possibly from foot foci by external circuits, or (*c*) primary hand infection with or without secondary foot involvement. A fourth group, we think, can now be added; viz., dermatitis due to some chemical or at least nonvital substance in conjunction with an active fungous infection, say on the feet. This possibility may explain the absence of fungi in some cases. This classification excludes the bacterial dermatoses which Mitchell[8] has described; and a recent case[9] studied apparently confirms these observations.

It is our aim in this paper to illustrate the basis for assuming this fourth group. This is a group in which, essentially, the fungus is only a predisposing factor, inducing what amounts to a hyperallergy. The following case reports are given to demonstrate specifically that the patients became sensitive to these substances only subsequent to the fungous attack; furthermore, that the fungous attack was unequivocally a new one (or had become decidedly active for the first time) and had not been obtained at previous dates when the patient had been subjected to these various substances. It is believed in these particular cases that the conditions in the patients were such that the symmetrical eruption on hands and the like would not have come out unless they had had elsewhere an active superficial fungous infection.

REPORT OF CASES

CASE 1.—*Original fungous infection on foot; sensitiveness to cottonseed oil.*

Mrs. H. R., aged 30, a housewife, admitted to the clinic, Oct. 17, 1928, had had an eruption on the right foot and on both hands for six years; the eruption appeared first on the plantar surface of the right foot and was considered a fungous infection. She said she had been treated by a dermatologist spasmodically for several months but had become unable to pay even moderate fees and was referred to the clinic. Dr. Stillians saw the patient several times and considered the eruption to be a ringworm infection. General physical examination was negative with the exception of a scar on the neck and large cryptic tonsils. The important item in her history was a thyroidectomy six years previous to admission.

The urine test was negative; the basal metabolic rate was within normal limits. Serologic examination of the blood was negative and the blood count was normal. Roentgen examinations of her teeth were negative.

When seen on June 6, 1929, she had an acute flare up on the hands and, because of the previous fungous infection, was restudied through the kindness of Dr. Stillians. At this time she had a typical clinical ringworm infection on the plantar surface of the right foot consisting of a group of deep seated vesicles. Hyphae were recovered by the usual potassium hydroxide digestion method; cultures were all negative. Blood cultures for fungi were negative during this and succeeding exacerbations. The eruption on the back of the fingers, hands and wrists was a diffuse erythematous one with considerable edema on the flexural surface of the arms and forearms but, curiously enough, did not fit in well with our numerous previous cases of either dermatophytids or actual fungous infections (e. g., with cryptococci in antecubital cases, as mentioned by Charles J. White and J. H. Swartz[10] in their comprehensive report, and by Cleveland White[11]).

Further inquiry revealed that the patient had embroidered with silk previous to this flare up, but testing with silk (contact and scratch methods) and a host of other possible substances (S. J. T.) was completely negative. Soothing applications soon produced a clinical cure of the forearms as it had done in previous attacks. It was still considered as a dermatophytid; nevertheless, additional tests were performed. Histamine tests in the circulatory clinic at Northwestern University by Dr. Géza de Takáts were negative and a repetition of the basal metabolism test again gave figures within normal limits.

The patient was seen several times within the next year with an occasional mild relapse of ringworm of the foot and flare up on the flexures of the arms and on the fingers from time to time. In the fall of 1930 she appeared with an acute erythematous flare up on the hands and arms as previously described and also on the sides of the neck and legs. This time, however, there was no discoverable activity on the feet; we felt that this practically eliminated its being primarily a dermatophytid and that it must be a sensitization eruption. A large series of tests was now performed with cottonseed oil strongly positive. All other substances were negative.

Thereafter, the patient's regular diet was maintained with the exception of all articles containing cottonseed oil. Further questioning revealed that, as far as she could remember, she had placed cottonseed oil in cake before each attack. (It had been eaten many times before the original ringworm eruption and had produced no disturbance.)

Elimination of the cottonseed oil has produced a clinical cure, and she has been followed closely to date. Fungicidal preparations are used occasionally on the feet as a prophylactic measure; clinically and microscopically the fungous infection has completely disappeared.

CASE 2.—*Ringworm of the finger and nail; sensitiveness to oatmeal.*

A school girl, aged 12, had had a fungous infection of the right index finger for several weeks, with many small thick roofed vesicles on the sides of the fingers. Hyphae were found on potassium hydroxide preparation, and eventually, on culture, *Trichophyton interdigitale* was grown. The condition on the finger was somewhat slow in responding to therapy but at the end of six weeks was practically healed. While the same preparations were being used, a discrete patchy erythematosquamous eruption appeared on all extremities.

Because of previous experience in this type of case, a sensitizations factor other than fungus was suspected. Examination of the secondarily affected areas resulted negatively for fungi; a blood culture was not taken because the patient objected.

Inquiry into the diet disclosed that she had begun to eat oatmeal the past few days (fall of the year) and that she had eaten oatmeal every winter for many years. Elimination of oatmeal from the diet produced a clinical cure. The fungous infection completely healed after several more weeks of treatment.

CASE 3.—*Fungous infection of foot; sensitiveness to buckwheat.*

A woman, aged 21, a college student, had had ringworm of the toes and plantar surface of her left foot for several months. When first observed, the patient said the condition was considerably better and improving, but she wanted advice as to a symmetrical patchy eczematous eruption on the back of her hands, forearms and thighs.

A few hyphae were found from the foot after considerable search; cultures were negative. As the fungous infection was undoubtedly improving and the secondary eruption of only a few days' standing, it was felt that the latter was due to some other cause.

Skin tests of many substances showed only buckwheat to be strongly positive. Further questioning revealed that she had started eating buckwheat cakes just previous to the last eruption. She had eaten them in other years with impunity.

CASE 4.—*Original infection on scalp; sensitiveness to silk.*

A high school girl, aged 15, had had an eruption on her face for one year and, according to her history, had received a great many roentgen treatments in that time. When first observed, the face was erythematous and edematous; the itching and burning was most intense. The scalp had many patchy, dry, scaling areas, fitting into the clinical diagnosis of seborrheic dermatitis.

The important observations in her history were that there were marked exacerbations on her face especially after attending dances, and that for a month previous to the onset of the face involvement she had had scaling areas in the scalp.

Skin tests were at once performed and she was found strongly sensitive to silk. Discontinuation of wearing silk and then desensitizing with silk has produced a clinical cure, combined with treatment to the scalp. Cultures from the scalp scales yielded *Monilia;* fungicidal therapy has clinically cleared that area.

Although various fungi and bacteria are believed to cause scaling dermatoses in the scalp, and although there are some who do not believe in the infectious origin of many cases of so-called seborrheic dermatitis, we felt justified in calling the scalp manifestation a superficial fungous infection. With extension to the face and eyelids and other structures, the skin there became sensitive to silk. At least, the findings, observations and therapeutic response would indicate such a possible theory. This case was cited because of its close association with other superficial fungous infections besides on the extremities, where the first observations were made.

In other cases, tomato was found as the offending substance in two, milk in one and chocolate in another. In several cases, multiple sensitization was elucidated.

TECHNIC OF SKIN TESTING

It is now generally conceded that many diseases are caused by sensitization to some protein, either epidermal, furs, food, pollen, bacteria or a miscellaneous group, such as orris root, pyrethrum, silk, kapok and cotton. We know that sensitization to one or more of these proteins may cause asthma, hay-fever, urticaria, eczema, angioneurotic edema, migraine and colitis. This sensitization or hypersensitiveness is determined by simple and painless skin tests.

There are four methods in use for performing these tests. First, the cutaneous or scratch test, which consists of making small linear cuts into the epidermis about one-eighth inch long and one inch apart, care being taken not to cut deep enough to draw blood. The forearms are usually selected for the scratches, but the back and thighs may also be used. A Graefe eye knife or any dull scalpel or even a large needle can be used to make the scratches. A small amount of the powdered protein is then placed on each scratch with the flat end of a tooth pick and a drop of tenth-normal sodium hydroxide is placed on the protein and rubbed in with the sharp end of a tooth pick. It is allowed to dry and after twenty minutes is wiped off with water and the reactions are read.

The second method is the intracutaneous or intradermal test, which is done by the injection of 0.05 cc. of the dissolved protein into the skin, raising a small wheal. This method is used when the scratch tests are all negative and in patients suspected of pollen, dust, animal emanations and other miscellaneous sensitizations. Fatal results occasionally occur with the intradermal tests, especially in patients with asthma or hay-fever who are extremely sensitive, or severe systemic reactions may occur. Therefore, it is not wise to use this method as a routine measure.

A third method which can be used to determine hypersensitivity is that of the passive transfer technic; blood is withdrawn from the patient and centrifugated at high speed. The serum is injected intradermally in a nonsensitive individual and skin tests are made over these areas. A positive test consists of an urticarial wheal, or, at times, an erythema occurring usually within five to thirty minutes. Delayed reactions may occur from eight to twelve hours later, particularly in food hypersensitiveness. About 200 of these proteins, exclusive of pollens, are available for testing each case of allergic disease.

A fourth method, the so-called patch test, is now being used with considerable help in discovering the cause of some obscure cases of dermatitis venenata. The method is extremely well illustrated in a recent paper by Sulzberger and Wise.[12] These various methods are detailed in a preliminary way on account of the application they may have in our problems in dermatophytosis.

SPECIAL ALLERGIC PHASES

1. *"Multiple" Sensitization.*—In a previous communication, one of us[13] reported an asthma caused by canary feather protein and an eczema caused by silk[14] in one and the same patient. Incidentally, such cases emphasize the importance of making a sufficiently varied set of tests on each patient and of not being content with the more common substances. This is called multiple sensitization; i. e., sensitization to any two or more *unrelated* substances.[15] This is different from "group" sensitization. Thus, patients who react to timothy pollen[16] usually react to other members of the *Gramineae* group, as red top grass, June grass and orchard grass. Likewise, patients reacting to the pollen of ragweed will usually also react to other members of the compositae, such as giant ragweed, sunflower and cocklebur. Brown[17] has named these "group reactions"; they are due to a similarity in the structure of the protein molecule.

2. *Balanced Allergy.*—There is yet another phase of allergy that may enter into the "dermatophytid" problem. A person may be sensitive to some protein, such as a food with which he comes in frequent contact, and yet remain free from symptoms. Peshkin and Rost[18] and Rackemann[19] have found that about 10 per cent of children without symptoms of allergy are sensitive to one protein or another. They are allergic but are held in equilibrium; the terminology "balanced allergic state" has been advanced by Vaughn.[20] In it tissues are able to handle a given amount of the allergen without upsetting the allergic balance; desensitization from eating small amounts of the allergen may be a factor in deferring symptoms. An overdose, now, of the allergen will upset the equilibrium with an onset of symptoms. One may be sensitive to two proteins, maintaining allergic balance while the contact is with only one but developing symptoms on exposure to both (summation effect). Hay-fever, asthma, urticaria and dermatitis subjects frequently show multiple sensitiveness.

COMMENT

The suggestive causative rôle of the original fungous infection in the genesis of a secondary sensitization phase has become easier to recognize as more cases have been observed and analyzed. It is readily admitted that there are a great many cases of "ringworm" of the hands and feet; only a few are accompanied or followed by a symmetrical eruption produced, fortuitously, by an extraneous substance. However, the same may be said of dermatophytid; only a few of the bona fide superficial fungous infections are accompanied by what are commonly accepted as dermatophytids. And, of course, from the opposite angle many cases of eczematoid dermatitis of the hands have been found sensitive to many substances in which there was no evidence of a previous active fungous infection.

In discussing the mosaic fungus, Williams[21] summarized quite succinctly the present status of toxic manifestations of superficial fungous infections. In part, he states that a dermatophytid is explained as the reaction of a sensitized skin either to organisms or to their toxins: the sine qua non in this explanation is the assumption of a preliminary sensitization of the skin. Further, he states that other facts point to the altered reaction of the skin as one of the most important factors in this disease. In many typical cases, a large proportion of the lesions on the feet contain the organism in scanty numbers or not at all, while in severe cases the finding of the organism is often excessively difficult or impossible. Some of the severe cases are accompanied, at or near the site of the original infection, by a severe but superficial dermatitis, which is usually sterile. The altered reaction of the skin, therefore, expresses itself in two ways: first, by hypersensitiveness to the poison of the disease and a variety of types of inflammatory response and, second, by a more or less complete destruction of the organism. Going further, Williams mentions the possibility that allergy in tinea may not be transient and may not disappear when the supply of toxin ceases, and that the reaction of the skin to external irritants may be permanently altered. All in all, he feels that the work of recent investigators has thrown considerable light on the problem; but much remains to be done. In theorizing the possibilities here, Sulzberger and Lewis's[22] observations are decidedly instructive and subjective. They say:

> The fact seems established that products of fungi are capable of causing an eczematous eruption in a hypersensitive skin. This seems important not only for the understanding of the pathogenesis of dermatophytids of the hands but also because it demonstrates that the products of other microorganisms may be capable of producing eczematous eruptions in hypersensitive persons.

All the foregoing points bring up a most probable clinical occurrence; viz., that in some people who have fungous infections the skin is so altered that it becomes sensitive to certain foods, external irritants, and the like, to which no previous clinical manifestations had ever occurred. In the light of our observations and excellent therapeutic responses when both phases are recognized, we believe this to occur definitely. Hence it is believed that an infection of the skin due to living organisms may likewise render the person hypersensitive to substances emanating from things inanimate as well as animate.

Apparent cure or a marked improvement of the fungous infections did not eradicate the secondary eruption, while removal of the incriminating substance from the diet or removal of the irritant was of distinct help, and in practically all produced a clinical cure.

Trichophytin was used in only one patient of this group; it produced such a marked aggravation of the ringworm infection that it was not felt justifiable to use it further. A statement of Sulzberger and Kerr[23] in this respect is significant. They state that "for a procedure (i. e., testing to trichophytin) which gives a large number of positives in apparently normal individuals cannot bear much weight in diagnosis; this has naturally led to a diminished belief in the diagnostic value of trichophytin in the United States." Its value, therefore, at present, in testing these sensitization dermatoses would be quite limited if of any value. Furthermore, in testing several patients in another line of research who at the time had undoubted ringworm of the feet, it was entirely negative (C. W.).

The discussion of the fundamental principles of allergy will not be undertaken here. The original meaning of Pirquet and Schick in 1906 may be recalled; viz., "A change occurring in an organism after contact with a living or inanimate organic 'poison' and manifesting itself in an altered reaction to a second application of the same substance (or closely related)." Various terms are used by various experts, which has led to considerable confusion. The term "sensitization" is used for want of a better one.

The skin tests must be properly executed and properly interpreted. If so, then the cause of the secondary eruption is quite simplified. Ramirez and Eller[24] state the situation quite tersely in saying that "sensitization tests are a distinct aid in the diagnosis of dermatoses if carefully performed and interpreted." In some instances one can detect the causative substance without the necessity of sensitization tests. Especial study in each of the observed patients in this group was made to determine that the sensitization occurred only after the preceding fungous activity. Thus it is felt that in these patients the active fungous infection had definitely sensitized them to the various extraneous substances.

CONCLUSIONS

Superficial fungous infections (ringworm) of the extremities and elsewhere may be followed by secondary sensitization dermatoses of nonfungous nature.

Such dermatoses may be confused with dermatophytid eruptions; future studies may show that some may be a part of a dermatophytid as at present conceived.

Detailed individual study and properly performed sensitization skin tests usually will discover the offending substances.

Four illustrative cases are cited; an insufficient number of cases has been studied to incriminate any specific organism or any particular class of proteins or substances.

ABSTRACT OF DISCUSSION

Dr. Albert Strickler, Philadelphia: I am impressed with the tremendous importance of the question of hypersensibility. It has not been many years since the question of hypersensibility was limited to the problem of drugs. The second step in the advance was the relationship of poison ivy, and the work of Bloch, and then this problem—important because of its wide spread—the trichophyton fungus infection. Dermatologists are faced with a peculiar problem, because there are many conditions on the skin, particularly on the hands, the etiology of which seems to be more or less uncertain, in the sense that no definite test is available which will determine whether the lesion is due to a trichophyton infection, whether the condition is one of mild or severe hypersensitiveness, or whether a trauma of some kind produced the skin lesion on the hand. At the Skin and Cancer Hospital we have attempted in the last several months to carry out several cutaneous tests with trichophytin. Unfortunately, perhaps because of experimental error, many were positive, so many that we could not believe our results. An important thing to keep in mind is the peculiar idiosyncrasy of the skin. Second, what are the drugs which the patient has either applied locally or taken internally? Third, what is the method by which a reaction on the skin may be obtained which will give a true etiologic index? The question of hypersensibility, and the question of finding a reliable cutaneous test for these trichophyton infections, present the important elements for consideration.

Dr. Joseph Muller, Worcester, Mass.: I was impressed by this paper, as I am working on allergy in general and have found several cases in which the patient did not react under one particular allergy but had a combined allergy. It was necessary to have two allergins present to get the allergic reaction. In one case, an allergic eczema in a girl, aged 12, the combination of potatoes and wheat was the cause of the disorder. Removal of either one from her diet for a prolonged period produced cure. A woman had urticaria from eating strawberries on some occasions but not always. I could not correlate it. After some time I got a calender which she kept on her menstrual periods and found that she was susceptible to strawberries only during the first two days of menstruation. Another case was that of a woman who had urticaria after eating five different foods and who promptly lost that allergic state after removal of her teeth. This case seemed to me parallel to the case reported by Drs. White and Taub in which trichophytin injection caused an eruption, combined with food or other materials.

Dr. S. W. Becker, Chicago: The authors have presented an excellent cross-section of the population in a large city, and I wish to present a more intensive study of a selected group of children. The University of Chicago has a small private school for pupils corresponding in age to those in public schools. Great care is observed with regard to children taking athletics and entering the swimming pool. Any child who has a maceration between the toes or an exfoliation between the toes is excluded. The parents commonly bring the children to us for an evaluation of the condition, and they are generally considerably perturbed. We have no Negroes, but children from the higher strata of society, and pediatricians state that we have children with what Tilbury Fox has termed dyshidrosis. These children are more prone to develop verrucous conditions. We have examined them repeatedly by potassium hydroxide and other methods and have found no fungus. We are inclined to believe that the diagnosis of fungus infection is extremely difficult, and the paper of Drs. White and Taub confirms this. Patients who are hypersensitive and develop a dermatitis have been found to be seven times as sensitive to fungi as normal individuals. We know that during their eruption they are many times more sensitive, so we would expect them to develop a dermatitis of the type the authors describe.

Dr. Samuel M. Peck, New York: I have been attempting to desensitize a series of patients. About twenty-four patients did not have dermatophytosis, so far as I could judge. My idea was that, given a case of trichophytin sensitivity, in order to treat trichophytosis with trichophytins the sine qua non was sensitization. Therefore, as a matter of choice I took patients who had not had trichophytosis, with the same idea as the treatment of hay fever in the preseasonal period, for I knew I was giving a certain amount of trichophytin, and therefore was using a logical amount of therapy. In the patients with a trichophytosis I got a desensitization, but they did not react to injections of Zurich trichophytin. These patients have returned in the last month with what I judge to be recurrence and now tests for the trichophyton are positive.

Dr. Marion B. Sulzberger, New York: The conclusions which I wish to reach concerning trichophytin desensitization are the following: It is not efficacious in the majority of cases with the technic now used, but it is sufficiently encouraging in the few cases I have witnessed to recommend it for use in epidermophytids that have proved recalcitrant to other therapy. In addition to this, I should like to try variations of administration, such as intravenous or subcutaneous injections. Concerning prophylaxis, it is impossible to think that one can achieve this by disinfecting clothes or floors or anything of the sort. Almost all have had and have tinea infections. Every one carries the fungi continually, whether walking on infected floors or disinfected floors, in sterile slippers or slipperless. One factor that reduces resistance to these germs is maceration. Hence the occurrence of manifest lesions after gymnasium work, swimming pools or golf, and after nervousness and its accompanying hyperhidrosis. In some cases the best hope for combating these outbreaks is by influencing the immunity, and one way of influencing this immunity is through trichophytin injections.

Dr. Cleveland J. White, Chicago: The clinical observation that one dermatitis may predispose a patient to another has been made by experienced dermatologists. Dr. Becker reported his observation that persons with a dermatitis venenata are more sensitive, especially during the duration of the dermatitis. It was the aim in this paper to try to prove definitely that such events do actually occur after the skin has been rendered allergic by an active ringworm infection, and a sensitization dermatitis due to an inanimate substance occurred. In an occasional case, even after both phases are recognized, local treatment is necessary in the secondary eczematoid areas because of irritation and possibly bacterial invasion.

THREE FATAL CASES OF BACILLUS PYOCYANEUS INFECTION *

B. S. KLINE, M.D.
AND
A. S. MASCHKE, M.D.
CLEVELAND

Three fatal cases of Bacillus pyocyaneus infection observed at Mount Sinai Hospital of Cleveland presented characteristic features, including gangrenous and less severe lesions of the skin, most advanced in the anal, rectal or genital areas; general intoxication with profound prostration and, at autopsy, hemorrhagic and necrotic lesions in the skin and viscera, associated with massive local bacterial colonization. One of these cases, which presented agranulocytosis, terminated eighteen days after the onset of symptoms in a previously healthy child.

B. pyocyaneus infection, although not of common occurrence, is perhaps less rare than is generally supposed. Clinically it may be confused with a number of skin diseases, including pellagra and lupus erythematosus disseminatus. It must be differentiated from aleukemic leukemia, the purpuras and other diseases. Some progress toward specific therapy has been reported by Wassermann,[1] and it is possible that further studies will reveal methods of preparing potent bactericidal and antitoxic serums.

Bacillus pyocyaneus was obtained by Gessard,[2] in 1882, in pure culture from two cases of skin wounds showing bluish green discoloration. Not long thereafter the organism was found, by numerous investigators, in colored suppurations in various portions of the body. Among the first reports was that of Gruber[3] in 1887, who recovered Bacillus pyocyaneus from green suppurations of the ear.

---

* From the Laboratory and Medical Departments, Mount Sinai Hospital.

[3] Gruber, J.: Ueber das vorkommen grunen Eiters in Ohre, Monatschr. f. Ohrenh. **21:** 145; 178, 1887.

By 1897 the organism had been repeatedly found not only in various local processes throughout the body but also in general infections with severe constitutional symptoms, as reported by Barker.[4] This observer also noted the occurrence of Bacillus pyocyaneus in gangrenous lesions of the skin, as did Hitschmann and Kreibich [5] shortly thereafter in similar cases of ecthyma gangrenosum.

A good review of the literature to 1908 concerning the pathogenicity for man of Bacillus pyocyaneus is given by Waite.[6]

A more comprehensive review of the literature to 1926, including the biology and pathogenicity of the organism, is presented by Lode.[7]

The few reports since 1926 concerning Bacillus pyocyaneus infection in man add nothing to the classic description of the disease by Eugen Fraenkel [8] in 1917.

REPORT OF CASES

CASE 1.—*History.*—E. O., a white woman, aged 39, admitted to the hospital, Aug. 8, 1923, complained of redness of the cheeks with itching, which had started seven weeks previously. She had suffered from asthenia and from transient pain in many joints for about two years. About seven weeks previously a rash appeared on her cheeks, which rapidly spread and involved almost the entire face down to the neck and chest. The eyelids and lips became swollen and the mouth sore. She had marked lassitude, asthenia and anorexia.

Physical Examination.—The patient was well developed and well nourished; the temperature and pulse were normal. The lesion on the face, involving both cheeks and the bridge of the nose, was indurated and purplish, and had a sharp line of demarcation, resembling closely the butterfly form of lupus erythematosus. There was, however, marked puffiness of the eyes and marked swelling of the lips. The mucous membrane of the mouth showed white patches on the lips and the gums; there was a deeper ulcer underneath the tongue; the uvula showed superficial ulcerations.

On the extensor surfaces of the forearms and the elbows there were small circular purplish papular areas, indurated, having a somewhat indolent appearance similar to the lesions on the face and neck. In the anogenital region there was an extensive superficial ulcerative lesion, moist and covered with a whitish exudate.

About fourteen days after the patient's admission a cough and dyspnea developed, and the temperature rose abruptly to 103 F. At this time physical examination showed dulness at both bases with many râles and other signs of consolidation. Death occurred, August 25, seventeen days after admission. Laboratory examinations showed a slight secondary anemia and, almost consistently, a leukopenia, the white cells varying from 7,000 down to 2,000, with a normal differential count. The urine was normal. Blood cultures were negative. Stools were negative for ova and parasites.

The clinical diagnosis vacillated between lupus erythematosus disseminatus and pellagra. The latter diagnosis was considered because of the previous history of asthenia, the depressed state of the individual, and the presence of indolent, rather symmetrical lesions, appearing for the most part on regions of the skin not covered by clothing. The patient's diet, however, except for the fact that she ate meat two or three times a week only, had been fairly well balanced, containing plenty of eggs, butter fat and fresh vegetables.

Autopsy.—Autopsy thirteen hours after death showed: Bacillus pyocyaneus infection with early gangrenous inflammation in the anovulvar region; multiple erythematous and maculopapular disseminated skin lesions (gram-negative bacilli in lesions); focal erythematous lesions in the oral cavity, larynx, esophagus, stomach and intestine; small ulcers of the lips, buccal mucosa and lower esophagus (gram-negative bacilli in lesions); coalescing lobular pneumonia (B. pyocyaneus was recovered from the pneumonic lung); old and fairly recent tuberculous inflammation of the peribronchial lymph nodes.

The body was that of a well developed, well nourished white woman. The skin showed lesions, as described. On section of the lungs, both upper lobes and the left lower lobe showed grayish areas of coalescing lobular consolidation. Mucosa of the upper anterior surface of the tongue, in an area about 2 cm. in diameter, showed considerable injection. In the posterior portion there was a punctate hemorrhage about 2 mm. in diameter in the mucosa. On the edge of each true vocal cord the larynx showed a small area of injection and possible infiltration several millimeters in large diameter.

Examination of the lower two thirds of the esophagus presented a striking picture. There were about a dozen circumscribed, finely injected areas, ranging from 2 mm. to 1 cm. in diameter. The injection in the majority of the lesions was concentric. Some of the areas showed grayish infiltration of the mucosa. Some showed definite central superficial ulceration. A few showed yellowish flecks at the edge of the ulcerated portions. Throughout the small intestine there were a number of areas of intense patchy injection of mucosa. The rectum showed fairly numerous areas of injection and some hemorrhage. In places the circumscribed injected areas resembled those in the esophagus.

Cultures from the consolidated lung yielded abundant growth of Bacillus pyocyaneus.

Under microscopic examination the following conditions were revealed: The skin of the vulvo-anal region showed areas of necrosis of the surface epithelium with chronic granulation tissue in the base. The skin of the foot showed numerous engorged capillaries in the upper layer of the corium, and a number with hyaline thrombi in the lumen (regional hemorrhages). Associated with these lesions, the granular cells in the rete were swollen and the cytoplasm was vacuolated. In several places there were vesicles within the rete. Sections of the lung showed a striking picture of apparently necrotizing bronchopneumonia. The necrosis affected the exudate and the walls and was observed in places involving smaller bronchial branches and their contained exudate. The esophagus showed an area of erosion several millimeters in extent, with chronic granulation tissue in the base. Throughout the section the blood vessels were engorged. Section of the rectum showed an area of ulceration at the mucocutaneous border, several millimeters in diameter, with chronic granulation tissue in the base

In early and moderately advanced lesions of the skin, lung and alimentary canal, sections stained by the Gram method showed clumps of large gram-negative bacilli.

CASE 2.—*History.*—F. E. D., a well developed, well nourished white man, aged 58, came to the hospital, Jan. 30, 1924, with the complaint of enuresis and frequency for the past two years. He had had night frequency for many years and for the past two years enuresis; he had been catheterized twice a day for the past two months.

Except for the urinary tract, his physical examination on admission gave negative results. The prostate on rectal palpation was large but not nodular. The urine was alkaline and contained many clumps of pus cells and epithelial cells. Chemical analysis of the blood and the phenolsulphonphthalein test gave negative results. Two weeks after admission he had a chill and his temperature went to 104 F.

The white cell count rose following the first chill to 41,000, with a normal differential count, and the nonprotein nitrogen went from 27 to 141 mg., with a corresponding increase in the various nitrogenous metabolites and dextrose; the phenolsulphonphthalein return fell to 15 per cent in three hours. Blood cultures were negative.

The patient was acutely sick, had numerous severe chills, and, despite transfusions, intravenous injections of mercurochrome-

220 soluble and supportive measures, he died, February 29, thirty days after admission.

Clinical diagnosis was hypertrophy of the prostate, atony of the bladder, cystitis and acute ascending pyelonephritis.

Autopsy.—Autopsy six hours after death showed: chronic prostatitis with enlarged median bar; dilatation and hypertrophy of the bladder: acute cystitis; ureteritis; bilateral suppurative pyelonephritis (Bacillus pyocyaneus and Staphylococcus aureus in the latter lesion); Bacillus pyocyaneus septicemia; gangrenous colitis and bronchopneumonia (Staphylococcus aureus also in the latter lesion).

The body was that of an anemic looking slightly emaciated tall old white man. In the right and left upper lobes of the lungs there were a number of dry granular grayish consolidated patches varying in size up to a centimeter in diameter.

The kidneys together weighed 550 Gm. The surface of each presented a striking picture with innumerable opaque yellow areas, from 1 to 3 mm. in diameter, slightly elevated above the general level. There was marked opaque yellow infiltration in places throughout the kidney substance. The mucosa of the ureters showed some injection. In the lumen there was abundant pus. The bladder contained a few hundred cubic centimeters of turbid urine. The walls were greatly thickened, averaging 1 cm. The mucosa was strikingly trabeculated and showed considerable injection, some areas of hemorrhage and apparently some infiltration of the mucosa. At the neck of the bladder there were two spherical masses of firm yellowish white tissue, apparently the median bar of the prostate, each 1.5 cm. in diameter, elevating the regional, considerably injected vesical mucosa and in addition obstructing the orifice. Each lateral lobe of the prostate was somewhat larger than the average. The consistency was somewhat increased. On section, some scarring of each lobe was seen. A few small spherical yellowish white nodules were present on each side.

Beginning in the cecum and continuing to the anal ring, especially marked in the rectum, there were areas of yellowish brown infiltration of the mucosa especially marked along the folds of the large intestine, with extensive ulceration in the sigmoid colon and the rectum. The odor was offensive.

Culture of the blood showed abundant growth of Bacillus pyocyaneus, and kidney culture showed Bacillus pyocyaneus and Staphylococcus aureus.

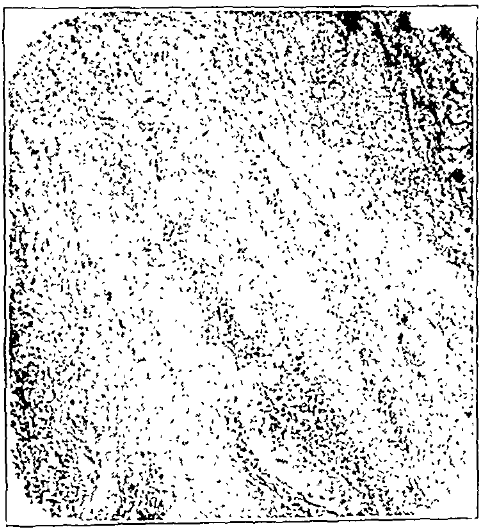

Fig. 1 (case 3).—Low power magnification showing gangrenous necrosis in primary lesion of anal region.

Under microscopic examination the following conditions were noted: Section of the lung showed typical necrotizing pneumonia. Section of the kidney showed intense infiltration by pus cells in all portions, with numerous abscesses varying in size up to 3 mm.

The colon presented a striking picture of necrosis of the mucosa and submucosa with intense pus cell infiltration, abundant fibrin deposit and thrombosed blood vessels.

The following observations were made on sections stained by the Gram method: Numerous large and small clusters of typical gram-positive staphylococci were seen in the lung. In certain necrotizing areas especially involving blood vessels there were many slender gram-negative bacilli.

In a gangrenous lesion in the colon there were innumerable slender gram-negative bacilli.

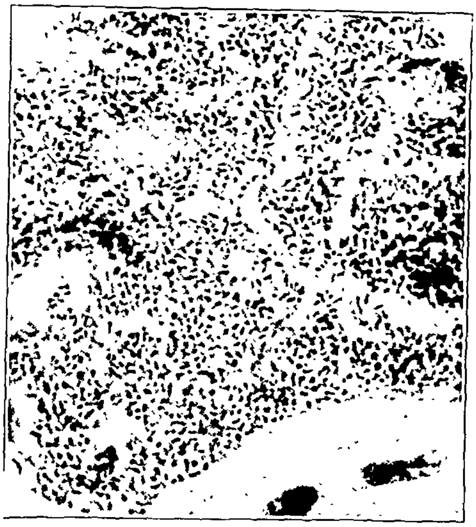

Fig. 2 (case 3).—High power magnification of lesion shown in figure 1. Note the massive colonization of Bacillus pyocyaneus with gangrenous necrosis.

In portions of a section of the kidney there were numerous slender gram-negative bacilli, especially in the interstitial tissue and in the walls of blood vessels. There were numerous gram-positive cocci in clusters in many areas of suppuration.

Case 3.—*History.*—W. G., a white boy, aged 7 years, admitted to the hospital, Sept. 21, 1928, complained of a high fever and of pain in the rectum of two days' duration. The family history was negative and, except for a history of an abscess under the arm one year previously and another near the rectum two years previously, the past history of the patient was essentially irrelevant

Physical Examination.—The child was well developed but slightly undernourished, with a hot, dry, pallid skin; the temperature was 104 F. The lungs were normal and the heart showed a slight bulkiness of the left ventricle on fluoroscopy. The spleen was palpable two fingerbreadths below the costal margin, and the liver was also palpable but not tender. The patient complained of extreme pain in the perineum, and there was very marked tenderness in that region. However, no swelling was palpated. Numerous hemorrhages were found in both retinas. The red blood count was 2,000,000; the hemoglobin, 55 per cent; platelets, 55,000; the white blood count 3,200, with 40 per cent granulocytes. Bleeding time and clotting time were normal. Urinalysis and the intracutaneous tuberculin test both gave negative results Cultures from the stool yielded an abundant growth of Bacillus pyocyaneus.

Course.—The patient's condition became gradually worse, the temperature remaining at a very high level; the pulse became more rapid, and the prostration increased. A few days after admission, a few purpuric spots appeared over the abdomen and the lower extremities. A faint systolic murmur was heard over the precordium and a slight to and fro friction rub in the third interspace to the left of the sternum.

Six days after admission, blood culture showed an abundant growth of Bacillus pyocyaneus. The white blood cells diminished in number to 1,150 and the granulocytes fell to 5 per cent. The blood platelets dropped to 14,400 and the red blood cells to 1,600,000. Transfusions were given twice with no apparent improvement. The next day a deep mass was palpated in the left ischiorectal area, bulging into the rectum. In a day or two the skin of this region became gangrenous, and an incision and drainage were done. The child became comatose, and a gangrenous sloughing area developed in the region of the first lower left molar, where a tooth had been extracted; physical signs of bronchopneumonia appeared over both bases and the patient died, October 6, sixteen days after admission to the hospital. The impression on admission was that the case was one of aleukemic leukemia, but after the positive blood culture a diagnosis was made of Bacillus pyocyaneus septicemia, gangrenous inflammation of the muscles of the left buttock, thrombocytopenia and agranulocytosis.

Autopsy.—Autopsy, performed by Dr. A. M. Young, fifteen and one-half hours after death showed: anorectal gangrene (B. pyocyaneus); gangrene of the muscles of the left buttock (B. pyocyaneus); B. pyocyaneus septicemia with focal necrotizing pneumonia; focal necrosis of the appendix; multiple hemorrhagic necroses, especially of the serous membranes.

There were a number of areas of bluish red discoloration beneath the skin of the trunk and extremities in places, apparently subcutaneous hemorrhages. There was considerable bluish red discoloration about the anus; there were also a number of large blebs containing reddish fluid.

When the abdomen was opened many punctate hemorrhages, ranging from 1 to 4 mm. in diameter were noted, scattered everywhere over the peritoneal surfaces. Numerous hemorrhages were disclosed in the pleura and in the diaphragm when the thorax was opened. Firm nodules were felt on palpation in all lobes of the lungs. On cutting down, these areas were found to be dark red with a central gray area. These areas, approximately 1 cm. in diameter, were roughly spherical. In the left upper lobe, on section there were several small, gray, somewhat translucent nodules, each about 6 mm. in large diameter, with an almost cartilaginous consistency. Section of the appendix showed grayish green mucosa, with a small defect in one area, approximately 1 mm. in diameter, covered by yellow friable material.

Near the region of the anus the colon showed marked edema, greenish discoloration of the mucosa and, in one area, ulceration of the mucosa with defect formation. The defect was covered by yellow friable material. Serosa of the alimentary canal throughout showed numerous areas of hemorrhage.

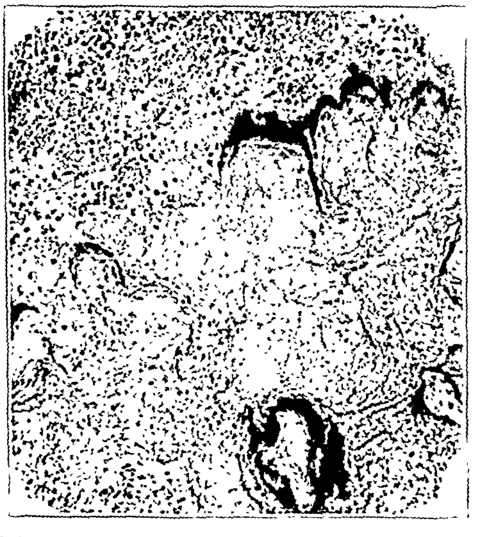

Fig. 3 (case 3).—Low power magnification of the lung. Note the fully developed embolic lesion with central necrosis and peripheral hemorrhage.

The muscles on the left side of the pelvis were swollen, reddish brown, much more friable than those on the right, and had a penetratingly foul odor. There was a surgical incision in the left buttock near the anal orifice, which communicated with the gangrenous muscles of the left buttock.

Smears from the necrotic lesion of the buttock showed innumerable gram-negative bacilli; small gram-positive chain forming cocci; larger gram-positive cocci, some of which were paired, and some fusiform bacilli.

Culture yielded an abundant growth of B. pyocyaneus, B. coli and a gram-positive bacillus; also a rounded chain-forming, small gram-positive coccus in broth.

Culture of the blood revealed B. pyocyaneus and B. coli-communior. A culture in broth yielded also a gram-positive chain-forming coccus (enterococcus?).

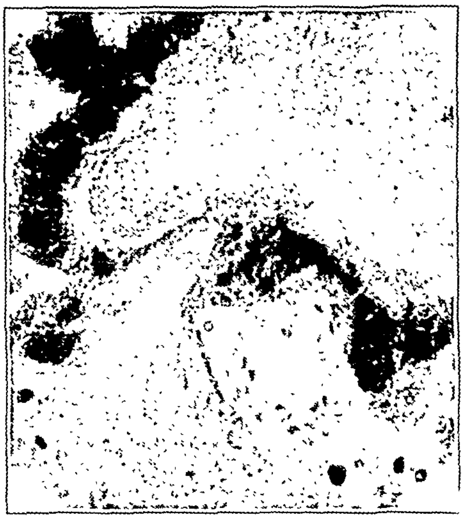

Fig. 4 (case 3).—High power magnification of section shown in figure 3, showing Bacillus pyocyaneus colonization with necrosis.

Microscopic examination of sections afforded the following data:

The anorectal tissue was scarcely recognizable. There was marked necrosis throughout. The material stained amorphous blue and pink. In places, phantoms of the former cell structures were recognizable. There was very slight infiltration throughout by round cells and a few polymorphonuclears.

The tissue of the gluteal muscle was scarcely recognizable There was marked necrosis throughout.

In the lung, section 1 showed a roughly circular area approximately 4 mm. in diameter, the center of which was necrotic, amorphous blue and pink stained with abundant fibrin present. There were marked hemorrhage into the alveoli about this necrotic area and moderate infiltration by round cells and a few polymorphonuclears. Section 2 showed several fairly large areas (3 to 5 mm.) of scarring with central necrosis. In one area the scar tissue was quite cellular.

On section the appendix showed a wedgeshaped area of necrosis of the mucosa. In places, phantoms of former cell structures were present.

Section of a peribronchial hilar lymph node showed an area of scarring similar to those seen in lungs. There was some central necrosis. At the periphery there were a few scattered foreign body giant cells.

Anorectal and gluteal lesions stained by the gram method showed innumerable gram-negative bacilli adjoining one another almost everywhere. Very little intact fixed tissue was present.

Gram stains of the lung revealed innumerable gram-negative bacilli in many blood vessels and alveoli in the necrotic area. Innumerable gram-negative bacilli were present in the necrotic area of the mucosa when the appendix was stained by the same method. A number of bacilli were present in the regional intact tissue.

CLINICAL OBSERVATIONS

Two acute cases and one quite chronic case showed:

1. The presence of gangrenous lesions in the anogenital region in all three cases.
2. Bacillus pyocyaneus septicemia in one of the acute cases.
3. A toxic appearance with severe prostration in all the cases.

4. Leukopenia in two cases; not present in the case with concurrent Staphylococcus aureus infection.

5. Agranulocytosis in one case. In this connection it is of interest to note that Bacillus pyocyaneus infection has been found present in a considerable number of the reported cases of agranulocytosis.

6. Thrombocytopenia in one case.

7. Ulcerative and erythematous lesions in the mouth in one case.

8. Indolent, erythematous, raised, sharply circumscribed skin lesions, varying in size from a few millimeters to a butterfly lesion 10 cm. in extent over the bridge of the nose in one case. The latter lesion suggested the diagnosis in this case of lupus erythematosus. The fact that many indolent lesions occurred in parts most often unprotected by clothing led to the belief that the condition might be pellagra. A case similar to this was reported by Ashby, Eldridge and Freeman.[9]

9. Terminal bronchopneumonia in the three cases.

PATHOLOGIC OBSERVATIONS

1. Gangrenous genital, anal or rectal inflammation was found in three cases.

2. Bacillus pyocyaneus septicemia was found in two cases.

3. Disseminated erythematous or necrotizing lesions of the alimentary canal were found in three cases. In one case there were multiple erythematous lesions in the esophagus, some with areas of necrosis. A case with even more severe involvement of the esophagus was reported by Barker[4] (case 3).

4. Scattered hemorrhages of the serous or mucous membranes were found in three cases.

5. Bacillus pyocyaneus bronchopneumonia was found in three cases. The pneumonic patches in one case were recognizably different from ordinary bronchopneumonia, the lesion consisting of a coherent coarsely granular gray core, from 1 to several millimeters in diameter, surrounded by an area of hemorrhage or of smooth, red consolidation. The lesions varied from 4 to 12 mm. in diameter.

6. Erythematous, macular, maculopapular and vesicular skin lesions were found in one case.

Microscopically, the primary anal and genital lesions at autopsy showed massive bacterial colonization, gram-negative bacilli (Bacillus pyocyaneus) predominating, with striking necrosis of the tissue. There was slight leukocytic infiltration in places.

Early embolic lesions showed gram-negative bacilli (Bacillus pyocyaneus) in the vessel walls, with regional hemorrhage and at times abundant fibrin deposit.

Fully developed embolic lesions showed a central necrotic core composed of necrotic fixed tissue, very few wandering cells, innumerable gram-negative bacilli, not only in the vessel walls but also in many places adjoining one another for considerable distances; at times there was abundant fibrin present in the core. In some fully developed embolic lesions there was abrupt transition to normal tissue. Gram-stained sections, however, showed gram-negative bacilli in cells beyond the necrotic zone. In others there was a zone of hemorrhage about the necrotic core. This unusual lesion is perhaps most characteristic in the lung.

Healed embolic lesions (lungs, peribronchial lymph nodes) were composed of masses of dense fibrous tissue (several millimeters in diameter) showing some round cell infiltration. Some showed areas of central necrosis and some showed giant cells in places.

INTRADERMAL IMMUNIZATION IN GONORRHEA

AN EXPERIMENTAL AND CLINICAL REPORT *

B. C. CORBUS, M.D.
CHICAGO

Stimulated by the publications of Besredka[1] on the streptococcus and staphylococcus "antivirus," and realizing the lack of standardization in the treatment of gonorrhea in men, women and children, I made a determined effort in the summer of 1928 to produce a similar product for the treatment of neisserian infections. Up to the present time there have been no published reports in German, English or American literature of any similar product having been produced from the gonococcus.

However, in 1927 Barbilian, Vosebeoinie and Franke[2] reported (in France) an experience in the treatment of gonococcal anterior urethritis by means of local injections of so-called antivirus. Sixteen men with acute gonorrhea were treated and fourteen were said to be clinically and bacteriologically cured. The gonococci were cultivated in an ascitic fluid medium. Bertarelli[3] (in Italy) made similar clinical experiments but his results were so discouraging that he gave up the use of antivirus preparation.

As it is very difficult to grow the gonococcus on a liquid medium, and as there was failure in producing a satisfactory growth, in the spring of 1929, the assistance of Clark and Ferry of the Research Department of Parke, Davis and Company was obtained. In the fall of 1929 a gonococcal bouillon filtrate was produced and given to us for clinical research. This was found by them to contain a soluble exotoxin and not to be an antivirus. In December, 1930, before the Society of American Bacteriologists they[4] presented their paper on studies of the properties of a bouillon filtrate of the gonococcus, the conclusions of which are as follows:

> 1. The gonococcus produces an extracellular toxin, when grown in suitable liquid medium, which promotes rapid development.
>
> 2. The sterile bouillon filtrate from young cultures contains this extracellular toxin in sufficient concentration to give positive skin reactions in dilutions of from 1:1,000 to 1:1,500.
>
> 3. Injection of animals with this toxin stimulates the formation of an antitoxin which will neutralize the toxin in vitro as well as in vivo.
>
> 4. Control autolysates and mechanically produced control intracellular extracts give negative skin reaction in low dilutions.
>
> 5. An antivirus which met the specifications of Besredka[1] was not produced in liquid cultures of the gonococcus allowed to incubate for six or seven days.

In preparing the gonococcus toxin (bouillon filtrate), cultures were allowed to incubate not longer than from four to six days, and the medium employed was prepared from veal infusion containing 0.1 per cent dextrose and 5 per cent ascitic fluid.

[4] Clark, L. T.; Ferry, N. S., and Steele, H. H.: Paper presented in December, 1930, before the Society of American Bacteriologists, J. Immunol. **21:** *233 (Sept.) 1931.*

In our early attempt with the bouillon filtrate we directed its application to the urethra in acute anterior urethritis in the male. Elaborate and carefully controlled means of sealing the bouillon into the urethral canal were devised, using it both in concentrated and in diluted form. Later copious urethral irrigations supplemented by hand injections were tried. After a thorough trial met with failure this method of procedure was abandoned.

INTRADERMAL INJECTION

Bearing in mind that Müller,[5] as early as 1922, had called attention to the fact that in gonorrheal urethritis in the male when he had injected intracutaneously small quantities of aolan, there resulted in a few hours a marked stimulation of the urethral secretion, we made an exhaustive review of the literature on intradermal medication. We found that during the last few years three methods of approach had been opened in the defensive mechanism of immunity in man. These comprise, first, the cells that are immunized (the reticulo-endothelial system); second, the route of injection of the immunizing agent (the skin), and, third, the immunizing agent (bacteria or their toxins).

Scientifically, the procedure of influencing disease by way of the skin was introduced in 1796 by Jenner,[6] who is justly called the founder of cutaneous therapy.

It has been known for some time that the skin is not only a simple sheath protector of the body but also an organ of vital importance in the production of immunity and the prevention of infection. It is composed of two very distinct parts considered from the embryologic as well as the histologic point of view; i. e., the epidermis, which is derived from the ectoblastic layer, and the derma, or cutis vera, which is derived from the mesoblastic layer. The derma, or cutis vera, is composed of a network of elastic fibers of great strength interlaced with connective tissue elements. The rich vascularity of this area makes it possible to bring large quantities of blood into the skin; at the same time the histiocytes of the loose connective tissue act as receptive cells.

THE RETICULO-ENDOTHELIAL SYSTEM

While these cells were recognized by Metchnikoff[7] in 1884 and called macrophages, it was not until Aschoff,[8] in 1924, emphasized the cellular mechanism of defense that characterized these cells that Metchnikoff's original conception of immunity was accepted as a rational defensive mechanism.

These cells comprise a large group of cellular elements that arise from the mesenchyme. At times they are very different under physiologic conditions, but their reaction is similar if not identical in response to certain stimuli. According to Maximow,[9] they are found in the spleen, liver, lungs (small amount), omentum, bone marrow, lymph nodes and loose connective tissue. Their nomenclature is varied and confusing, being designated as Kupffer cells in the liver, splenocytes in the spleen, clasmatocytes in the omentum, dust cells in the lung, histiocytes in the lymph nodes and macrophages in the loose connective tissue. In this paper the term histiocytes, as suggested by Maximow, will be used.

All histiocytes play an important rôle in metabolism and are capable of wandering. However, this is manifest only under the influence of stimuli, either local or general.

Whatever irritates the skin, either mechanical or bacterial in nature, not only irritates the histiocytic elements but also sets in motion involuntary nervous stimuli which, according to E. F. Müller,[5] is an equally important factor in the body's resistance to disease, as it is from this vital center that the whole physical mechanism of defense is controlled. His experiments led him to believe "that the entrance of bacterial excitants into the body cause a reaction involving chiefly two groups, (1) the bone marrow system, the originator of the white blood corpuscles, and (2) the involuntary nervous system, the conductor not only of the stimulation from the site of infection to the bone marrow system, but also of the newly formed immunizing substances and leukocytes to the site of infection." This is shown clinically by a leukocytosis during infection of the body.

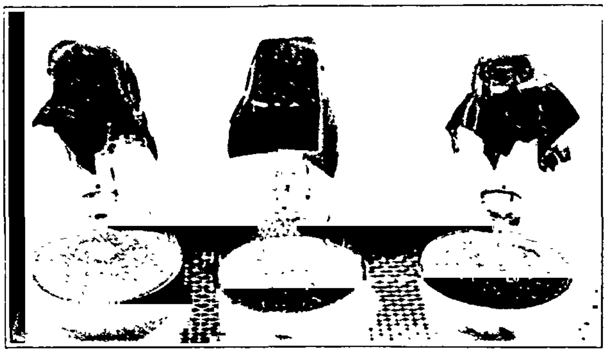

Fig. 1.—Gonococcus growing on liquid culture medium

He also claims that the skin acts as an amplifier of specific and nonspecific irritants (proteins), and that the response to stimuli introduced intradermally is from 100 to 150 times greater than that produced by any other route.

Although intradermal injections of autogenous gonococcal vaccine have been used with favorable results in gonorrhea by Ryll-Nardzewski[10] and others, it autolyzes too readily to make it a stable therapeutic procedure.

Max A. Goldzieher and Samuel M. Peck,[11] in their experiments on the reticulo-endothelial system, have shown that the histiocytes of the skin respond more quickly to the toxins of the bacteria than to the bacteria themselves.

In consideration of the foregoing data we concluded that if a suitable gonococcal toxin could be prepared and injected intradermally, satisfactory results might be obtained. To our knowledge this is the first attempt to cure acute and chronic neisserian infection by the intradermal administration of a gonococcal toxin (antigen).

CLINICAL REPORT

Since November, 1929, in the private practice of Dr. Vincent J. O'Conor and myself, there have been treated by means of intradermal injections of the

gonococcus bouillon filtrate 195 persons in various stages of gonorrheal infection.

These were classified at their initial examination as follows: Men: acute, 86; subacute, 23; chronic, 42; total number of men treated, 151. Women: acute, 10; subacute, 5; chronic, 29; total number of women treated, 44. In addition, there were three girl babies treated solely by this method.

The shortest period in which the gonococcus was continuously absent from the secretions in the acute and subacute condition in the male was four weeks. In the acute infections in the female the shortest period was nine weeks. In chronic male infection the shortest period was one week; in the female, nine weeks. The longest period of observation in the male was ten months; this patient is still uncured. In the female, the longest period of observation was thirteen weeks. The general average from the initial injection to the apparent complete riddance of the gonococcus in acute urethritis in the male was ten weeks; in the female, twelve weeks. In chronic infection the period of treatment necessary to eliminate the gonococcus was considerably shorter than in the acute cases. This was equally true in men and in women. This was apparently due to the fact that the gonococci were localized in such areas as the urethral glands, the prostate and seminal vesicles in the male and in Skene's, Bartholin's and the endocervical glands in the female.

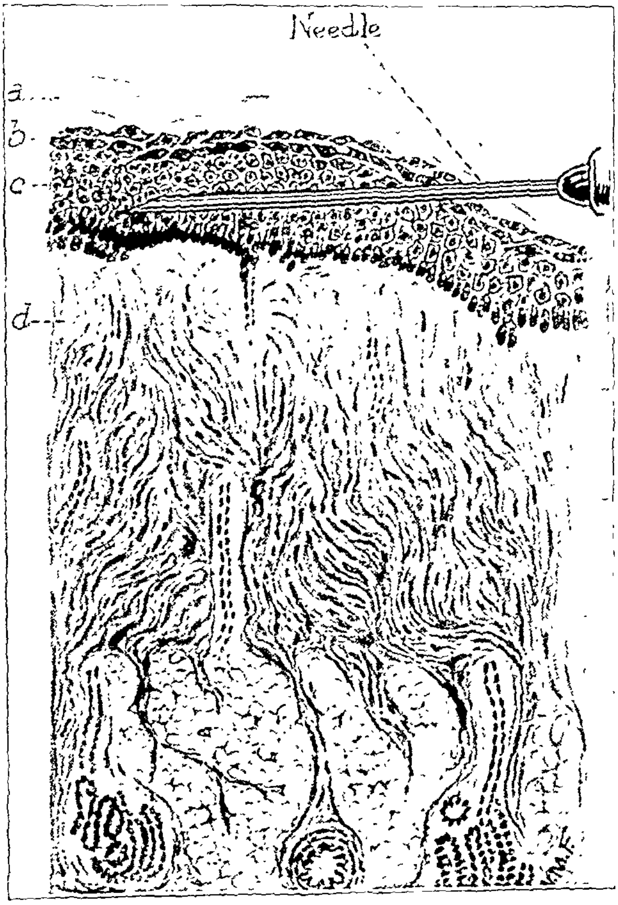

Fig. 2.—Section of the skin of the palm of the hand (reduced from a drawing with a magnification of about 150 diameters), showing site of intradermal injection: *a*, stratum corneum; *b*, stratum granulosum; *c*, stratum malpighii; *d*, stratum corium and fibrous bundles.

In this series are included five persons with gonorrheal arthritis; in every case the symptoms rapidly disappeared with intradermal medication and prostatic and seminal vesicle massage.

At the outset, owing to injections of too great an amount of bouillon filtrate, we occasionally produced a severe reaction in the male urethra which resulted in congestion and edema and at times acute posterior infection with a larger percentage of prostatitis and epididymitis than usual. With a more careful administration of dosage we have not only avoided these reactions but we have been able to reduce markedly the percentage of complications as compared with our previous methods of treatment.

In only two patients has there been any reaction suggestive of an anaphylaxis. These were of mild degree. Injections have been resumed after varying periods without untoward effect. In all, something over 2,500 injections have been given, the quantity varying from 0.1 cc. to 3 cc. per dose. The maximum dose now given is 1 cc., as described in detail elsewhere. The majority of patients have only a slight systemic reaction. Locally there is always a certain amount of discomfort at the site of injection, which continues for from twenty-four to seventy-two hours.

In some instances there is a slight febrile reaction for twenty-four hours. The temperature rarely rises above 100 F., and there is a mild toxic general effect.

The complement fixation test for gonorrhea, while not constant after an apparent complete immunization, was positive in a large number of patients.

Acute Gonorrhea in Men and Women

Duration of Infection	Size of Dose, Cc.
3- 7 days (1 week)	0.10
7-14 days (2 weeks)	0.25
14-21 days (3 weeks)	0.35
21-28 days (4 weeks)	0.50
28-35 days (5 weeks)	0.75
35-42 days (6 weeks)	1

No clinical research, however convincing, would be complete without having used the culture medium as an antigen.

From March 15 to June 1, 1931, twelve patients have been under observation at the Evanston Social Hygiene Dispensary. All these patients received intradermal injections of the culture medium. Two subacute and three chronic cases were followed consistently from week to week. While there was a salutary influence on some, the presence of the gonococcus in the discharge was easily demonstrable in all. Because of the irregular attendance and the shortness of the time of observation, no conclusions can be drawn from the other seven cases.

INDICATIONS AND DIRECTIONS FOR USING GONOCOCCAL BOUILLON FILTRATE

Gonococcal bouillon filtrate is indicated in acute and chronic neisserian infections in men, women and children.

It has been possible to standardize the dosage of the bouillon filtrate to meet every requirement.

The size of the first dose is in direct proportion to the duration of the infection.

The scale of dosage in the accompanying table ensures rapid immunization with no untoward effects.

The technic of intradermal injections is discussed later.

The size of the dose for the duration of infection is given in the table. For example, if the duration of the patient's infection is from three to seven days the initial dose would be 0.1 cc. Each succeeding weekly dose is increased in accordance with the scale given in the table until 1 cc. is given. If the duration of the infection is from twenty-eight to thirty-five days the initial dose would be 0.75 cc., increasing the following week to 1 cc.

When the dosage has reached 1 cc. in any case, this amount is continued at weekly intervals for from four to seven weeks until there is a clinical cure. It is always well to continue the injections for two weeks at least after the disappearance of the gonococcus; should there be a recurrence at this time, the intradermal injections may be resumed.

APPEARANCE OF DISCHARGE DURING TREATMENT

As this is active immunization and not passive, the discharge may not disappear until the fifth to the eighth week, or until at least from three to seven injections intradermally of 1 cc. at weekly intervals have been given, and it may not cease then; it may only cease entirely when there are no more organisms present and all injections have been suspended.

SUSCEPTIBILITY OF THE PATIENT

Occasionally following the dosage as outlined in the table, there is a severe local reaction in the urethra (local swelling, tenderness and inability to void). When this occurs, the size of the last injection given should be repeated after seven days and then increased, the next succeeding dose being used as outlined in the scale.

If an epididymitis occurs, the size of the last injection should be repeated in three days, to be followed in seven days by the next succeeding dose as outlined in the scale.

When there is prostatic involvement the usual procedure of massage should be followed; however, this should not be done until the acute symptoms have subsided and then not more frequently than at three to five day intervals.

SUBACUTE AND CHRONIC GONORRHEA IN MEN AND WOMEN

In every patient in whom the duration of the infection has been more than six weeks, an initial 0.5 cc. is given intradermally the first week and weekly injections of 1 cc. are continued until there is a clinical cure. Usually from six to eight weekly injections of 1 cc. will suffice.

Occasionally when severe edema and swelling of the urethra has persisted, it may be well to start with an initial dose of less than 0.5 cc.

When the prostate and the seminal vesicles are involved, prostatic and vesicle massage is indicated, the same as in acute cases.

GONORRHEAL ARTHRITIS

Gonorrheal arthritis is the most frequent type of metastatic gonorrhea. Almost any joint in the body may be affected and frequently the involvement is multiple. There is often present an accompanying synovitis, tenosynovitis or bursitis.

The knee joint is most frequently involved, but infection of the metatarsal, ankle, wrist, elbow, hip and shoulder joints also occur and are more frequent in the order given.

If gonorrheal arthritis occurs during the course of an acute gonorrhea, there is no difficulty in establishing the correct diagnosis. It is to be emphasized, however, that many chronically inflamed joints are diagnosed as "chronic gonorrheal arthritides." Gonorrheal arthritis may be recurrent but it is not, strictly speaking, chronic. When such a condition is chronic it is the result of adhesions and structural changes remaining as the result of previous acute gonorrheal inflammation.

In gonorrheal arthritis the complement fixation test on the blood is always positive if properly performed. In the absence of a positive test, and with negative smears and cultural observations from the genito-urinary tract, it must be concluded that active gonorrheal infection does not exist.

Frequently a septic infection from the teeth or tonsils is disregarded because the patient gives a history of a previous gonorrhea, and this evidence is unduly magnified as the possible etiologic factor of an acute arthritis.

The dose given here is the same as that described under subacute and chronic gonorrhea.

It is understood that the joints are to be immobilized and prostatic and vesicle massage instituted, together with the administration of the bouillon filtrate.

GONORRHEAL SALPINGITIS

The patient should be in bed and kept there until acute symptoms subside. Here the dose as outlined in the scale should be strictly adhered to. If the duration of the infection is more than six weeks, the initial dose should be 0.5 cc., followed by weekly injections of 1 cc.

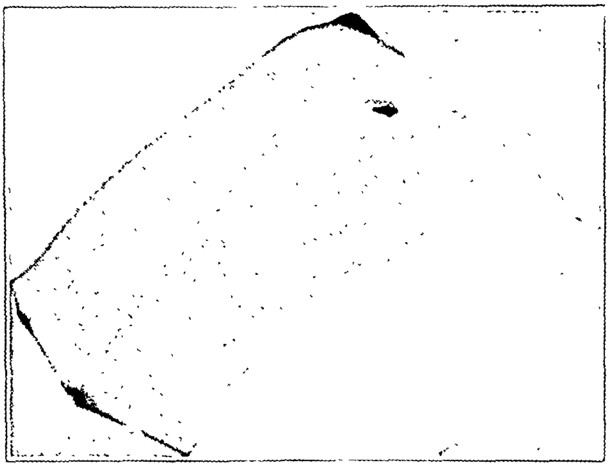

Fig. 3.—Arthus phenomenon. With repeated injections of an antigen in the same place in the skin, local tissue immunity occurs. This becomes so solid from the inflammatory reaction around the site of injection of the foreign protein that the injected material no longer gets into the circulation and eventually produces necrosis. The illustration shows the author's patient who had received seven injections intradermally of 1 cc. of gonococcal bouillon filtrate in approximately the same area in the thigh

INFECTIONS IN SKENE'S AND BERTHOLIN'S GLANDS

Directions as outlined for gonorrheal salpingitis should be followed.

NONGONORRHEAL INFECTIONS

Since the gonococcal bouillon filtrate is a specific for neisserian infections and no other infections, it is absolutely necessary that a positive diagnosis of gonorrhea has been made before instituting treatment. It should not be used unless one is sure of the diagnosis It is not a "cure all" for all urethral infections.

GONORRHEA IN CHILDREN

In gonorrhea in children, aged from 1 to 10 years the size of dose given for the duration of infection is as follows: 0.05 cc. for one week; 0.1 cc. for two weeks;

0.2 cc. for three weeks, and 0.25 cc. for four weeks. Then the dose of 0.25 cc. is continued once a week until the child is clinically cured.

As children show a hypersensitive reaction to intracutaneous injections, severe local irritation with bleeding may occur, if the dose has been too large. In this case the dose should be reduced for children showing such reactions as well as children, aged from 1 to 5 years, diluting the bouillon filtrate with an equal amount of sterile saline solution if necessary.

Caution should always be used not to increase the dosage too fast if there is considerable local irritation.

TECHNIC OF INTRADERMAL INJECTIONS

Any ordinary tuberculin syringe graduated in twentieths of a cubic centimeter will suffice. However, it is important to have a fine needle, preferably a 25 gage.

The most suitable site for injection is on the extensor surfaces of the arms and thighs. (In women the injections are given in the thighs.)

The needle is introduced parallel to the skin surface. As the thickness of the epidermis on the flexor surface is only about 0.2 mm., care should be used to advance the needle slowly with the oblique side upward into the papillary layer for about 0.5 to 0.75 mm. When the injection has been correctly placed, there appears a nontranslucent wheal, alabaster white, sharply circumscribed with a rose pink border, the needle shimmering through the epidermis.

ARTHUS PHENOMENON [12]

With repeated injections of an antigen in the same place in the skin, local tissue immunity apparently occurs. This becomes so solid from the inflammatory reaction around the site of injection of the foreign protein, that the injected material no longer gets into the circulation and eventually produces necrosis. This anaphylactic inflammation occurs, according to Opie,[12] because antigen and antibody have met in the tissue. This is known as the Arthus phenomenon.

In order to obtain general and not local tissue immunity it is advisable to put succeeding intradermal injections at least 6 inches apart from any previous injection.

55 East Washington Street.

ABSTRACT OF DISCUSSION

Dr. R. D. Herrold, Chicago: Dr. Corbus calls attention again to the fact that a great deal can be accomplished in gonorrhea without excessive local medication. Several years ago, working with this product and other bacterial vaccines, I was impressed by the marked improvement of patients who were getting only one local treatment daily as compared with the patients I had been treating three or four times a day. I feel that all would obtain better results, as I am at present, by not permitting any patient to use a syringe, himself, for local treatment, and by giving one injection daily or every two or three days. This must be taken into consideration in evaluation of a series of cases without such overtreatment. In treatment locally, one does not expect to get antiseptic action but stimulation of cells, and here I believe that the cells are stimulated sufficiently by injection every other day. These cells are probably some of the endothelial cells, such as the histiocytes. I shall consider first the product itself. After thorough experiment, I am convinced that the toxic substance in the broth is not essentially different from the autolyzed gonococcus, and therefore if the potency is the same the results will be the same, particularly if it is autolyzed in broth. One must distinguish between different immunologic reactions in the sense of obtaining an antibody that neutralizes toxin. This takes a period longer than seven days, and it is particularly significant that some immunizations, notably typhoid, which has stood the test of years, were produced by the subcutaneous route. Its potency per volume is similar to gonococcus. However, the local stimulation by intracutaneous injection suggests to me nonspecific benefit, and I believe it is entirely possible that such stimulation may be obtained, if of equal potency, by the typhoid toxin. Finally, in the control of a series of such cases one should include some nonspecific observations, and also one should not stop here in the effort to obtain a better biologic or chemical therapeutic measure in the treatment of gonorrhea, but should use this as the stepping stone since disagreeable reactions occur from gonococcic toxin, particularly with 1 cc. of a potency that will give a skin reaction with a dilution of 1 : 1,000.

Dr. P. S. Pelouze, Philadelphia: Dr. Corbus is to be congratulated on a valuable piece of experimental work. One should not lose sight of the fact that it is definitely experimental, however. Enthusiasm has been aroused so many times by various new treatments for this disease, only to be followed by disappointment, that it would be well to weigh new methods carefully. In this work, serious question could be raised regarding some of the arguments put forward. The proof of the value of any form of treatment rests in one's clinical experiences with it, and in judging the value of intradermal injections of Dr. Corbus' filtrate one is forced to use as standards the results obtainable by the best forms of treatment now existing. And, surely, so far as the time required to eradicate the gonococcus from the male is concerned, it is, by his own statements to me, much inferior to those treatments which have been in use. He informs me that his treatment eradicates the gonococcus in those cases in which only the anterior urethra is infected, rarely in six weeks and usually in from ten to twelve weeks. Our gently carried out local treatments to the urethra of the cooperating male usually accomplish this in six weeks. He further stated to me that it takes his method from six to eight weeks to banish the gonococcus from the patient with a posterior infection who has reached a stage wherein attack of the prostatic infection is safe. One can rarely find the gonococcus in the male who has had prostatic massage for that length of time. True, he still has infection kept up by secondarily invading bacteria, and needs further treatment. This is true also with Dr. Corbus' treatment. Considering the wide circulation of papers read at this meeting, it would be a great misfortune to allow ourselves and others to be too greatly impressed with the value of a treatment for gonorrhea which is so admittedly in its experimental stage that its makers do not feel sufficiently convinced of its value even to place the substance on the market. Particularly is this true when its seeming results compare so poorly with the results that can be obtained by other means.

Dr. Leo L. Michel, New York: About seven years ago, working in my clinic at the Hospital for Joint Diseases, I called attention to the good results obtained with the nonspecific protein. I reported that, following the intravenous injection of paratyphoid vaccines in acute gonorrheal arthritis, the joint pain and inflammation quickly subsided and the urethral discharge decreased. The course consisted of four injections of paratyphoid vaccine intravenously at intervals of from three to four days, though not infrequently the pain disappeared after the first injection. I was especially impressed with the complete disappearance of the gonococcus from the urethral secretions in cases in which I used this therapy. The results depended on the severity of the reactions obtained. The temperature had to be raised to 103 F. or higher; the severer the reactions were, the better were the results. This experience led me to try the intravenous nonspecific therapy in the acute gonorrheal infections. I had good results in a series of thirty cases, curing them in an average of from two to three weeks. I then ran into a series of failures. The failures were chiefly in the anterior gonorrheal infections; as a rule, the posterior infections responded. Just why this is so I cannot answer. It perhaps is analogous to the fact that this therapy is a failure in the gonorrheal periarthritis inflammation acting only in the inflammation of the articular joint. I never hesitate to use the nonspecific therapy in acute or in chronic anterior or posterior gonorrhea when time is a factor, if there are no contraindications.

[12] Opie, E. L.: Pathogenesis of the Specific Inflammatory Reaction of Immunized Animals (Arthus Phenomenon): the Relation of Local "Sensitization" to Immunity, J. Immunol. 9: 259, 1924.

DR. A. I. FOLSOM, Dallas, Texas: Dr. Corbus gave me a lot of this solution and asked me to try it in my clinic. We have not yet tried it carefully but have limited it to the chronic cases, that group showing definite clinical manifestations, by which we might show the results of the thing, and I must say that Dr. King, my associate, who has had to do most of the work, is definitely impressed with the clinical value of the method in the chronic complications of gonorrhea. However, we are finding now that by varying the method of injection we are getting distinctly better results in the same type of case as compared with the old subcutaneous or intramuscular injections of milk. We are injecting a small dose of sterile milk intradermally in several areas rather than in one, and it seems to us that probably some of the results may be due to the difference in the method of administration rather than in the intrinsic value of the milk itself. Our experience is entirely too limited to make anything other than simply a suggestion in this direction.

DR. BUDD C. CORBUS, Chicago: Answering Dr. Pelouze concerning the length of time required to cure a given case of gonorrhea, I presume that he is referring to the treatment of gonorrheal infection in the male when he compares the intradermal injection of the gonococcal toxin and other methods of treatment. One must remember that one is using active immunization and not passive. In acute infection, immunization can only be accomplished slowly. On the other hand, in chronic infections, in which the gonococcus is localized, larger doses of toxin permit a more rapid, generalized immunization. The standardization of a method of treatment in acute gonorrheal infection, that requires only weekly injections for from eight to twelve weeks to produce a cure, is far superior to any other method with which I am familiar. The history of the management of gonorrheal infection in women and children is a sad story. Everything known in the realm of antiseptics has been tried. Unfortunately, in a large number of cases the gonococcal infected female remains infected until time and her own resistance finally put an end to the infection. It is just in this class of cases that standardized intradermal immunization with the gonococcal toxin produces the most brilliant results. In regard to Dr. Folsom's work, any nonspecific protein stimulates the reticulo-endothelial system, but a specific protein, either bacteria or their toxins, not only stimulates the reticulo-endothelial system but in addition causes formation of a specific antitoxin which, through the humoral and cellular defensive mechanism of the body, cures these infections. A new era is dawning in the treatment of all infections of the urinary tract. The treatment of colon bacillus pyelonephritis and cystitis by the local injection through a catheter of colon bacillus toxin has been favorably endorsed by Heitz-Boyer, LeFur, Mezeran, myself and others. The treatment of Hunner's ulcer has run the gamut of almost everything known in the realm of therapy. My experience has been most impressive with the removal of focal infection and the combined local applications and intradermal injections of the toxin of the specific organism present. The skin, as an immunizing organ, is far superior to that of any other organ in the body. Here the rich vascular supply of the true skin not only facilitates the formation of protecting substances but also acts as a depot for their dissemination to other parts of the body.

The "Strawberry" Gallbladder.—Moynihan, in 1909, first called attention to small yellowish spots like sand or grit on the mucosa of the gallbladder. In such cases he noticed also that the bile sometimes shimmered because of the presence of cholesterol crystals. . . . Boyd published the first detailed study of the pathology of this remarkable condition. He demonstrated the lipoid nature of the white or yellow deposits that are seen with the naked eye in striking contrast to the dark red background of the rest of the mucosa. By histologic and chemical means he also showed that these lipoid-like deposits were cholesterol, an observation, however, that Lichtwitz was really the first to make.—Elman, Robert; and Graham, E. A.: *Arch. Surg.* **24**:14 (Jan.) 1932.

IODOBISMITOL

A SOLUBLE BISMUTH PRODUCT FOR USE IN THE TREATMENT OF SYPHILIS: PRELIMINARY REPORT [*]

P. J. HANZLIK, M.D.
H. G. MEHRTENS, M.D.
CHARLES GURCHOT, PH.D.
AND
C. C. JOHNSON, M.D.
WITH THE ASSISTANCE OF JEAN SPAULDING, A.M.,
AND D. C. MARSHALL, M.D.
SAN FRANCISCO

In our program of studies of antisyphilitic remedies, attempts have been made to test the possibilities for penetration of the brain by certain products. If an antisyphilitic agent could be depended on to do this, the prevention and treatment of neurosyphilis would begin at the time of treatment of acute syphilis. This mode of attack on neurosyphilis is desirable, since it is now accepted that Spirochaeta pallida invades the central nervous system early in the course of the disease. The commonly used antisyphilitic drugs cannot be depended on to penetrate the central nervous system without some previous treatment of the patient to increase the efficiency of penetration. Obviously, if a drug could penetrate unaided, the treatment would have decided advantages. The object of this report is to present a preliminary survey of results with a bismuth product which we have found to penetrate the brain.

The bismuth compounds in current use contain the bismuth as cation, or in basic form. The majority of reports in the literature state that bismuth is not present in the cerebrospinal fluid after the use of compounds of this type, and our results with such products, in very large doses, agree with those of the literature. The few positive results that have been reported are not convincing because of doubtful chemical tests or analytic procedures; and, in some instances, unusual quantities of bismuth are reported.

It is known that the anions bromide and iodide can penetrate the brain and appear in the cerebrospinal fluid, especially after meningeal irritation. In relation to the blood, the cerebrospinal fluid contains more anions and fewer cations. It is claimed by Strecker,[1] who quotes the work of others, that the diffusible cations do not penetrate as readily as the anions, thus suggesting a high order of penetrating efficiency of the latter. Of the ionizable organic salts, the salicyl anion is known to appear in the cerebrospinal fluid. This generalization with regard to anions, however, does not apply to such organic compounds as alcohol and methenamine (hexamethylenetetramine), which do not ionize but yet can appear in the cerebrospinal fluid. Since bismuth, as cation, does not readily penetrate the central nervous system and appear in the cerebrospinal fluid, it occurred to us to test the possibilities of bismuth, as anion. Furthermore, if this ion were combined with a penetrating anion, such as iodine, the

possibility of a successful outcome with the bismuth appeared stronger. The presence of iodine in such a product would contribute to antisyphilitic action, if anything.

Although compounds of bismuth, as anion, or in acid form, are not commonly described in textbooks on chemistry, and are unknown to many chemists, such compounds are described in larger and special treatises.[2] The existence of bismuth in this form is more than plausible from the grouping of bismuth with arsenic and antimony in the periodic table. The facts are that bismuth is really a metalloid and is capable of existing as cation or anion in definite compounds. One of the anion, or acidic, compounds is obtainable in the market, namely, sodium bismuthate ($NaBiO_3$), the sodium salt of bismuthic acid. We have tried this compound in a short series of experiments and have demonstrated the presence of bismuth in the brains of animals, but it is practically insoluble in all ordinary and special solvents, and, after injection, remains as an unabsorbable depot.[3] On account of these objectionable features, further work with the bismuthate has been postponed until more promising leads have been explored.

The other anion, or acidic, bismuth compound is the hydro-iodobismuthous acid, which together with its potassium salt was first prepared by Arppe[4] in 1845. A review of the literature showed that a number of salts and esters of this acid had been prepared, but the information in most cases was meager, incomplete or indefinite; and generally the physical constants of the compounds were not given. Some authors gave crystallographic constants. Pending a summary of the literature on this subject in a separate paper, it will suffice to state here that the object of chemists, in preparing some of these compounds, was to verify the position of bismuth in the periodic system; i. e., its close association with arsenic and antimony. This was done generally by complicated and tedious methods of synthesis. It appeared that some of the products described might be mixtures rather than definite compounds, and others impure compounds, but the existence of certain isomorphous compounds (iodo-arsenite and iodo-antimonite)[5] made the claims of anionic bismuth convincing.

The first task was to prepare in pure form certain compounds which appeared promising for our use, and to identify the bismuth as anion. For this purpose, the sodium iodobismuthite was chosen. The chlor-, brom-, and sulfocyanbismuthites have been prepared, and also certain esters of iodobismuthite, but this report is limited to the sodium iodobismuthite. Since the compound is dissolved in ethylene glycol, the abbreviated name "iodobismitol," which indicates the essential chemical composition and suggests the solvent, has been adopted for the product. The following abstract gives a summary of the essentials of its chemical composition, properties and pharmacologic and clinical actions. The details will be published later, possibly in several papers, but it is believed that a summary is in order at this time in view of our promising results, and because it is desirable to obtain clinical data on a larger scale than we alone could possibly obtain for a long time.

METHOD OF PREPARATION AND PROPERTIES

Briefly, sodium iodobismuthite is prepared by the addition of a small excess of dry sodium iodide to a saturated solution of bismuth chloride or bismuth iodide, which, however, is not easily obtainable in the market, in anhydrous ethyl acetate until the reaction is complete. The whole is filtered to remove any sodium chloride or iodide, which is insoluble in ethyl acetate, and the filtrate is evaporated with the aid of a current of air at room temperature. The dry residue is treated with 95 per cent alcohol to form a concentrated solution and allowed to crystallize. The supernatant alcoholic solution is decanted and the crystals are dried at room temperature. The crystals are monoclinic and a brilliant red. Sufficient crystals to give a concentration of 6 per cent are dissolved directly in cold ethylene glycol, commonly known as glycol, containing 12 per cent of sodium iodide (dry). This solution is the iodobismitol. It is placed directly, without sterilization, into clean glass ampules containing 2 cc. each, for use by intramuscular injection.

Several iodobismuthites are possible, but we have limited ourselves to the crystals separating out from alcohol. According to chemical analysis of these crystals, the bismuth content is 23.5 per cent (average). When the product is more exactly controlled and purified, by appropriate measures, the final crystals appear to consist of a single compound with a bismuth content of 21.5 per cent (average) and the empiric formula appears to be $Na_2BiI_5 4H_2O$. The colored ion migrates to the anode without liberation of iodine and therefore the bismuth exists as anion, whereas the bismuth of bismuth sodium tartrate, in 25 per cent sucrose solution, migrates to the cathode and therefore would appear to exist in the latter compound as a cation. The question whether the iodobismuthite may be regarded as a double salt, in the older sense of potassium mercuric iodide, may be answered in the negative for reasons already mentioned, and also because the ionic migration of the mercury in potassium mercuric iodide is similar; i. e., the mercury migrates to the anode (positive pole). In these compounds, the metals exist as complex ions. The name "iodobismuthite" is, of course, well established in chemical researches on bismuth.[2] This matter is not pertinent here and will be discussed in a separate paper on the chemistry of iodobismuthite. Iodobismuthite is a reducing agent in alkaline solutions. The crystals give concentrated solutions in water without hydrolysis, and these may be diluted in the presence of sodium iodide, but dilution with water alone causes hydrolysis and precipitation. On the other hand, the crystals dissolve readily in glycol alone without hydrolysis, and the solution can be diluted with water within certain limits without turbidity. A certain amount of the glycol solution, but not of an aqueous solution, can be added to whole serum without precipitation, and with the addition of iodide the precipitation is prevented, so that a 23 per cent solution of iodobismitol in whole horse serum will not result in precipitation or will cause only a faint turbidity, and the color becomes yellowish. Aqueous solutions when injected are precipitated in the muscles, cause pain and irritation, and give irregular absorption, whereas the glycol solutions leave no yellowish precipitate or only a very slight one, and are practically nonirritating.

The effect of iodide varies with the conditions of usage. Used with iodobismuthite in glycol, a concentration of 10 per cent iodide is sufficient to prevent precipitation of whole serum (the end-concentration of iodide in the mixture is about 1.5 per cent), but this will vary with the quantities of both serum and iodobismitol. The addition of iodide to the serum first and then of the iodobismuthite in glycol requires much more iodide to prevent precipitation. In life experiments on guinea-pigs, 10 per cent iodide with iodobismuthite in glycol gave slight precipitation at the site of injection in some animals, but 12 per cent iodide resulted in no evidences of precipitation, and therefore the 12 per cent concentration was adopted.

Other solvents for iodobismuthite besides glycol are glycerol, propylene glycol, alcohol and ethyl acetate, but not ether, chloroform, carbon disulphide, petroleum benzin, fixed oils and liquid petrolatum. Of these solvents, only the glycerol offered immediate possibilities as a vehicle for injection, but comparisons with glycol in patients showed that from 2 to 3 cc. quantities of glycerol were somewhat more irritating and painful than the same quantities of glycol; in fact, injections of glycol were generally no more objectionable than the introduction of the needle alone. Moreover, glycol is more mobile (less viscous), spreads more readily and evenly, is easier to handle, and is more antiseptic and apparently less toxic than glycerol.[6] Therefore, the choice of solvent fell on glycol. In glycol, the iodobismuthite is not dissociated and it is partly in chemical combination, since the bismuth compound can be distilled and, after extraction with chloroform or ether and evaporation of the chloroform or ether of the extract, a reddish brown residue remains containing the organic compound. These properties explain, in part at least, the comparative nonirritant action of the glycol solution. The iodide prevents precipitation and hydrolysis and thus promotes absorption of the compound, but in what form exactly we are not prepared to state. Thus, the use of glycol as a solvent permits the use of an inorganic compound of bismuth for injection. Other bismuth and metallic salts will probably be found to be soluble in glycol, but we have not found the subcarbonate, subnitrate and subgallate of bismuth, and bismuth sodium tartrate (Searle) to dissolve. Bismuth salicylate dissolves to a small extent after heating, but, on cooling, separates out. After solution with the aid of alkali, the tartrate, subgallate and subsalicylate can be freely diluted with glycol without precipitation.

ACTIONS OF IODOBISMITOL

Local Irritation.—This has been found to be so small as to be practically negligible with doses coming within the therapeutic range injected intramuscularly. Many patients have been unable to discriminate between injection of the product and injection of a corresponding volume of glycol, but a difference from a corresponding volume of saline solution could be recognized by the presence of some local soreness which, however, disappears quickly, so that patients have no objection to repeated injections. One of us (C. C. J.) who received an intramuscular injection of iodobismitol experienced only a slight burning sensation locally for about one hour without any other changes later. There have been no demonstrable local inflammatory changes and no abscesses among a total of 120 patients to date receiving repeated injections; only five patients, who had received many previous injections of mercury or of bismuth or were in poor condition from advanced syphilis, had some local induration following a number of injections of iodobismitol. Some few patients have complained of a greater local, though temporary, burning sensation than others. Other bismuth products in aqueous and oily mediums have not been as well tolerated and have caused local changes. Dozens of guinea-pigs, rabbits and rats have been injected with corresponding and higher doses of iodobismitol without evidences of local irritation or abscess formation. With the highest doses and with concentrations above 30 per cent of the compound employed in determining fatal dosage, some hardening of muscle and local precipitation has been found, but these conditions do not obtain in therapeutic usage. In rabbits, iodobismitol caused some lacrimation, slight hyperemia and a slight and temporary chemosis, which was indistinguishable from that of glycol alone, whereas the same strength of iodobismuthite and iodide in water caused definite chemosis, and iodide in water did not. Accordingly, there would seem to be some small degree of irritation in sensitive regions, such as the conjunctiva or mucosa, but not in muscle, in sensitive individuals and in those with lowered tissue resistance.

Toxicity.—Thirty-nine of forty adult patients have received total quantities up to 2.2 Gm. of the compound (with and without iodide), equivalent to 0.519 Gm. of bismuth, within three weeks without evidences of systemic toxicity, one injection being given every three days. Among the remaining eighty patients, many have received total quantities up to 6.4 Gm. of compound (1.5 Gm. of bismuth) over longer periods without demonstrable injury. Guinea-pigs receiving total doses of from 5 to 115 mg. (bismuth ion) per kilogram of the compound intramuscularly, in divided doses over periods of from seven to sixty-one days, showed the usual fluctuations, or no changes, in body weight. Albuminuria has not been demonstrated, even in two patients who showed salivation—one patient after 1.2 Gm. of the compound in ten injections on alternate days, and the other, after 2.16 Gm. in eighteen injections. The kidneys have been examined after repeated small doses in guinea-pigs with the following results: no demonstrable changes after a total of 20 mg. of iodobismuthite (4.72 mg. of bismuth) per kilogram; after from 37 to 82 mg. (from 8.7 to 19.4 mg. of bismuth), variable, moderate congestion and cloudy swelling; above 82 mg. per kilogram, marked congestion and cloudy swelling. The total therapeutic dose in a man weighing 70 Kg. and receiving one course of ten 2 cc. injections, or 1.2 Gm. of iodobismuthite, the equivalent of about 4 mg. of bismuth per kilogram, is about four fifths of, and after twenty 2 cc. injections, or 2.4 Gm. of iodobismuthite, equivalent to 8.1 mg. of bismuth per kilogram, only three fifths more than the doses which gave no demonstrable changes in guinea-pigs. After four courses of ten 2 cc. doses, or 4.8 Gm. of iodobismuthite, equivalent to 16.18 mg. of bismuth per kilogram, the total dose would be about equal to the median dose causing variable and moderate congestion. Since a large part of the bismuth is excreted, it would appear that three or four courses spaced by short intervals could be given with safety so far as renal irritation is concerned. Other experiments and clinical observations, which we hope to report separately, show that the dosage of glycol in iodobismitol, used in single and repeated doses, is far too small to cause the experimental oxaluria or calculi of very high and toxic doses reported in the literature; in small doses the glycol is presumably completely oxidized in the body.

The determination of fatal doses of iodobismitol in animals has thus far given certain difficulties owing to the large volumes necessary in which the toxicity of glycol must be considered. The following dosages have been obtained with iodobismitol intramuscularly: The minimal fatal dose in rats was about 0.106 Gm. of iodobismuthite (24 mg. of bismuth) per kilogram, and in rabbits more than 0.127 Gm. of iodobismuthite (30 mg. of bismuth) per kilogram. With 10 per cent iodobismuthite in glycol alone, the minimal fatal dose in rats was less than 0.13 Gm. (30.7 mg. of bismuth) per kilogram. Solutions of iodobismuthite in glycerol gave somewhat smaller fatal doses than the glycol solutions. The use of very concentrated solutions (from 30 to 50 per cent) in glycol or glycerol caused precipitation and irregular absorption, with a consequent increase in the size of the fatal dosage. Intravenously, the fatal doses of iodobismitol were as follows: The minimal fatal dose in rats was about 0.03 Gm. (7 mg. of bismuth) per kilogram, and in rabbits about 0.063 Gm. (14.9 mg. of bismuth) per kilogram. Iodobismuthite without iodide caused embolism. The data are being amplified in several ways, but, in general, the margin of safety is sufficiently indicated by the fact that the intramuscular fatal dose of iodobismuthite was about 62 times, and the intravenous fatal dose about 18 times, the single therapeutic dose. *Intravenously, the toxicity of iodobismuthite appears to be no greater than that of the bismuth sodium tartrate* (Searle). From these results, and also from the fact that intravenous injections of 3 cc. quantities in three patients were symptomless, subjectively and objectively, accidental vein injection should not be harmful.

---

[6] Fuller: J. Indust. & Engin. Chem. 16: 624, 1924.

Absorption and Excretion.—Fifty-nine of sixty-three guinea-pigs receiving daily divided doses within the therapeutic range, i. e., from 5 to 115 mg. per kilogram, with a sojourn of the compound of from seven to fifty-one days, have shown either no evidences of the compound at the site of injection or only a slight yellowish color in the muscles. Four patients receiving up to 2.2 Gm. (0.519 Gm. of bismuth), in from twelve to eighteen divided doses, showed no shadows on roentgen examination of the injected areas one month and six weeks after the last injection. One patient who had received twenty doses on alternate days showed slight shadows in three or four of the injection sites at the end of the twentieth injection. Two patients showed no shadows six hours, and one, two and three days after injection of single doses of 2 cc. Correlated with these results, which suggest a rather complete and rapid absorption, is a high urinary excretion of bismuth. Two ambulatory human subjects receiving a total of 0.1 Gm. each of iodobismuthite (0.0236 Gm. of bismuth) excreted 75 and 80 per cent of the total administered at the end of twenty-four days. A rabbit excreted 44 per cent of 0.043 Gm. (0.01 Gm. of bismuth) at the end of twenty-two days. The data in other subjects and rabbits are not yet complete, but all the results point to a more rapid excretion of bismuth than after the bismuth metal and bismuth compounds in oil. In general, the total urinary excretion of bismuth after iodobismitol compares with that after bismuth sodium tartrate (Searle), which has given a median of about 45 per cent after similar doses; i. e., after 0.03 Gm. of compound, equal to 0.022 Gm. of bismuth, but the rate of excretion may be slower.

As to the form in which the bismuth of the iodobismitol is absorbed and excreted, nothing is known, but we hope to investigate these questions later. A part of the compound is undoubtedly hydrolized at the site of injection, but it is believed that a part is absorbed as such. The yellow precipitate occurring locally on muscle suggests the hydrolysis, but this is by no means always present, except with very high concentrations.

Penetration of the Brain.—This has been the main object of attention in our experimental work. The results have been obtained mainly in guinea-pigs and rabbits given injections mostly in doses falling within the therapeutic range, thus differing from most results of the literature, which have been obtained with toxic and fatal doses of other bismuth products. Of forty-one guinea-pigs receiving the iodobismuthite in glycol, with and without iodide, in doses of from 19.6 to 451 mg. (equivalent to from 4.6 to 106.4 mg., median 17.2 mg., of bismuth) per kilogram intramuscularly, in daily divided doses during periods of from five to thirty-nine days (median, eighteen days), thirty-eight, or 92.7 per cent, showed the presence of bismuth in the brain and blood. The amounts demonstrated ranged from about 0.003 to 0.7 mg. (median about 0.1 mg.) of bismuth per hundred grams of brain. Of eight rabbits receiving subtoxic and fatal doses (from 164 to 1,300 mg., the equivalent of from 38.7 to 306.8 mg. of bismuth per kilogram intramuscularly) during periods of from one to seventy-three (median, six) days, all showed bismuth in the brain, as did also seven out of eight rabbits receiving the iodobismitol intravenously. The rabbits given intramuscular injections showed a median of about 0.2 mg. of bismuth per hundred grams of brain, and those intravenously, less; i. e., about 0.08 mg. These quantities of bismuth appear small, but it must be borne in mind that the total dosage employed, particularly in guinea-pigs, was small.

The accuracy of the method permitted the recovery of added quantities of bismuth coming within the range of the results after iodobismuthite. The added precaution was employed of analyzing simultaneously the bismuth content of the blood, liver, kidney and brain and eliminating all experiments in which the kidney did not show the largest amount of bismuth per gram. Except for an occasional accident in analysis, it was invariably true that the kidney contained the most bismuth, thus indicating a typical distribution of bismuth after iodobismuthite as after other bismuth compounds. The concentration of bismuth in the brains of about one-half the number of guinea-pigs was somewhat less than in the blood, but in the remaining half it was the same or somewhat higher (median, 0.1 mg. in 100 Gm. of blood, or 1 : 1,000,000). This suggests a fairly even distribution between the blood and brain. The brain content of bismuth could not be due to the blood of the brain, since the latter contains only about 1.24 per cent of its weight of blood (Vierordt). It was not possible to obtain sufficient cerebrospinal fluid from the animals for analysis, but the spinal fluid of one rabbit gave a positive test for bismuth. In two moribund patients injected with iodobismuthite, the brains showed the presence of bismuth. How much of the bismuth appears in the brain as cation, and how much as anion combined with iodine, is not known.

Cerebrospinal Fluid of Human Subjects.—Of forty human subjects with cerebrospinal syphilis or dementia praecox, thirty-seven, or about 92 per cent, showed the presence of bismuth. The quantities in the positive cases ranged from 0.001 to 1.162 mg. of bismuth per hundred cubic centimeters (median, 0.005 mg., or about 1 : 20,000,000 concentration). This low concentration would be expected, since the most that could be in the tissues is a concentration of 1 : 2,650,000 of bismuth after a single dose of iodobismitol, and of 1 : 265,000 after ten doses, on the assumption of complete absorption and retention. However, most of the bismuth is excreted, so that if only about one-fifth the total given remains in the body, the bismuth concentration in the brain may be closer to 1 : 10,000,000, which makes the low concentration found by us in cerebrospinal fluid understandable. These tissue concentrations of bismuth after iodobismitol would be comparable with those after the dosage of bismuth necessary for antisyphilitic action, according to Lomholt,[7] who suggests 0.5 mg. of bismuth per kilogram daily (1 : 2,000,000), and a total dosage of 5 mg. of bismuth per kilogram (1 : 200,000). The total dosage of the iodobismuthite in glycol, with and without iodide, was from 0.7 to 2.2 Gm. (median, 1.71 Gm., or 0.404 Gm. of bismuth) intramuscularly in from three to twelve divided doses. In six patients, the bismuth was demonstrated in the cerebrospinal fluid at the end of eighteen days after the injection of the first dose of iodobismuthite, and bismuth was still present in the spinal fluid two weeks after the last dose was given. Although the quantities of bismuth in cerebrospinal fluid were small and variable, there is no doubt that positive tests, at least for bismuth, were obtained in the great majority of subjects, and iodide was not indispensable to the appearance of the metal.

On the other hand, thirteen out of seventeen cerebrospinal fluids from as many patients receiving total doses of from 0.2 to 16.9 Gm. (median, 9.2 Gm.) of bismuth in the form of bismuth metal, potassium bismuth tartrate in oil or bismuth salicylate in oil, in divided doses intramuscularly, showed no bismuth and two of the four positive tests were doubtful. The dosage of bismuth in the latter patients was, of course, much greater than that in the patients receiving the iodobismuthite. The doses of iodobismuthite per kilogram in the animals were about twice the doses of the compound in patients. Therefore, it is planned to increase the dosage in patients with the view to increasing the content of bismuth in the brain and cerebrospinal fluid, although this may not ultimately prove desirable or necessary, since the antisyphilitic concentration of bismuth is exceedingly minute. The results obtained thus far with iodobismitol indicate that the product can be depended on to penetrate the brain in the majority of individuals.

After most of our work with older products of bismuth and iodobismuthite had been completed or started, bismuth sodium tartrate (Searle) was accepted for New and Nonofficial Remedies. Experiments with this water-soluble bismuth, with and without the administration of iodide, are under way in both man and animals to see how the cerebral penetration of this bismuth product will compare with the iodobismuthite, but the results are too incomplete to warrant a statement at this time.

Antisyphilitic Action.—Iodobismitol has been tested for its action on syphilitic virus in the experimental syphilis of rabbits and in clinical syphilis with definite effects. In thirteen rabbits that were used in prophylactic experiments on scrotal chancres, iodobismuthite, in doses of from 0.03 to 0.2 Gm. per kilogram intramuscularly, prevented the appearance of lesions during a period of three months, whereas seven untreated rabbits showed fully developed lesions containing spirochetes at the end of from sixteen to thirty days. Pairs of rabbits treated with bismuth sodium tartrate (0.01 Gm. per kilogram) and sodium bismuthate (0.032 and 1 Gm. per kilogram) intramuscularly showed no lesions during periods of from three to six months. Of two rabbits treated with neoarsphenamine intravenously (0.025 Gm. per kilogram), one showed positive lesions at the end of fifty-four days. Lymph node transfers from the rabbits receiving iodobismuthite (over 0.03 Gm.), bismuthate and bismuth sodium tartrate were negative, but the majority of untreated controls were positive.

In curative experiments on rabbits with developed chancres, using all drugs per kilogram intravenously in weekly injections for from two to three weeks, the results were as follows: After iodobismuthite, 0.04 to 0.1 Gm., the lesions in thirteen rabbits were free from spirochetes in twenty-four to forty-eight hours and healed in from two to five weeks earlier than the controls. In ten rabbits receiving total doses of from 0.015 to 0.0375 Gm., the acute lesions were unaffected. In pairs of rabbits after bismuth sodium tartrate, 0.025 Gm., the lesions were spirochete-free at the end of forty-eight hours and healing occurred at the end of seventeen days; after bismuthate, 0.4 Gm., the lesions cleared at the end of seventy-two hours and healed at the end of twenty-one days; after neoarsphenamine, 0.075 Gm., intravenously, the lesions cleared at the end of four hours and healed at the end of nineteen days. The lesions of the twelve untreated controls showed spirochetes until the end of twenty-eight days and did not heal until the end of forty-nine days (medians). Lymph node transfers from the majority of rabbits receiving a total of 0.05 Gm. and over of iodobismuthite per kilogram were negative at the end of three months, but a considerable proportion of those receiving less than 0.04 Gm. per kilogram and most of the untreated controls were positive. Lymph node transfers after the other drugs were not obtained.

Our results in clinical syphilis are limited on account of the difficulties of obtaining acute, untreated cases. The clinical material under the direction of one of us (H. G. M.) does not yield such cases and the work must be delegated to others. The following data were obtained for us by Drs. H. E. Alderson and Esteban Reyes of the Stanford Dermatological Clinic. Each patient received 2 cc. of iodobismitol, containing 0.12 Gm. of iodobismuthite, every three days. Patient G. G., with symptoms of primary syphilis and spirochetes in a tonsillar ulcer, responded with clearing of the spirochetes and healing of the lesions at the end of the third injection of iodobismitol (total, 0.36 Gm. of iodobismuthite). Patient V. E., with secondary syphilis, responded with clearing of the spirochetes from papules at the end of the third injection (0.36 Gm. of iodobismuthite), and healing of skin lesions at the end of five injections (0.6 Gm. of iodobismuthite). Patient W. W., with symptoms of secondary syphilis, responded with disappearance of the roseola at the end of the fourth injection (0.48 Gm. of iodobismuthite). The Wassermann reaction has remained positive, but full courses of treatment have not yet been given and negative tests would not yet be expected. The injections have been tolerated without local or systemic reactions. After this summary was in proof, Drs. Alderson and Reyes reported that clearing and healing of acute lesions in eight additional patients occurred after from three to thirteen (average five) injections of iodobismitol; the Wassermann reaction remained positive in positive cases and negative in the negative cases.

---

[7] Lomholt: Brit. M. J. 2: 887 (Nov. 16) 1929.

The main value of our results in experimental and clinical syphilis is the demonstration of a definite spirocheticidal action of the bismuth in iodobismitol. This would be expected of an absorbable bismuth product. As for the efficiency and permanence of the curative action, the results with iodobismitol may be expected to be the same as with any readily absorbable bismuth. In neurosyphilis, it is reasonable to believe that fully as much and more may be expected of iodobismitol, since our results indicate the appearance of bismuth in the brain and cerebrospinal fluid. The impression of one of us (H. G. M.), based on results with fifty patients to date, is that iodobismitol is certainly as effective as, and probably superior to, other bismuth products, but a longer trial and more cases are necessary before a definite opinion can be given. Consequently, iodobismitol would seem peculiarly adapted to the prevention and treatment of neurosyphilis from the beginning of the treatment of acute syphilis. Whether such treatment should be combined with the arsphenamines is a matter that does not come within the scope of this paper.

PROPOSED DOSAGE

The following dosage is proposed on the basis of our experience to date: Two cubic centimeters of iodobismitol should be injected intramuscularly thrice weekly, the needle being emptied with a little air and the part being gently massaged after each injection. Two days should be left free between injections. Up to ten or twelve successive injections may be given within four weeks as a single course of treatment, and from three to four courses, with periods of about two weeks' rest between courses. As stated in the text, bismuth has been demonstrated in the cerebrospinal fluid after a course of ten injections. In case of salivation or stomatitis, the injections should be stopped and a short period of recovery allowed. These signs in the mouth are the inevitable result of effective bismuth therapy and do not necessarily call for special treatment unless severe.

In a recent review of bismuth compounds used in the treatment of syphilis, Lomholt[7] suggests, on the basis of extensive experience, that the daily dose for antisyphilitic action should be the equivalent of about 0.5 mg. of bismuth per kilogram of body weight, and that a total of from 4 to 5 mg. of bismuth per kilogram should be given in one course. It will be seen that the proposed dose of iodobismitol agrees closely with Lomholt's recommendation; namely, the equivalent of 0.47 mg. of bismuth per kilogram for a person weighing 60 Kg., or 0.41 mg. for one weighing 70 Kg., and a total of 4.5 or 4.1 mg. per kilogram during a single course of ten injections. For various reasons, Lomholt indicates a preference for the bismuth oxychloride in suspension. Iodobismitol is hydrolyzed, in part at least, to a related compound, bismuth oxyiodide, which would act similarly to the oxychloride. Hence, it appears to be more than a coincidence that the oxychloride should, through empiric choice, possess desirable properties, in view of our results with the iodobismitol.

CONCLUSIONS

1. A preliminary report is submitted on the properties and actions of iodobismitol, a soluble and injectable preparation of bismuth, containing the bismuth as anion. Theoretical considerations for using bismuth in this form are given.

2. Iodobismitol consists of sodium iodobismuthite (6 per cent) dissolved in ethylene glycol containing sodium iodide (12 per cent). It is injected intramuscularly in doses of 2 cc. containing 0.12 Gm. of iodobismuthite (equal to 0.0236 Gm. of bismuth), a proposed course of treatment consisting of ten injections in about three weeks, to be followed by a rest period and additional courses as further experience may indicate.

3. Used in doses within the therapeutic range, iodobismitol was found to be generally well tolerated locally and systemically, to be fairly rapidly absorbed and excreted, to possess antisyphilitic action, to penetrate the brain of animals, and to appear in the cerebrospinal fluid of human subjects.

Accordingly, iodobismitol possesses certain advantages over the bismuth products in current use which contain the bismuth as cation and do not dependably penetrate the brain.

4. Iodobismitol appears worthy of clinical trial in the treatment of syphilis since it offers the possibility of early treatment, and of prevention, of neurosyphilis.

NARCOLEPSY

RESULTS OF TREATMENT WITH EPHEDRINE SULPHATE *

JOHN B. DOYLE, M.D.
AND
LUMAN E. DANIELS, M.D.
Fellow in Neurology, the Mayo Foundation
ROCHESTER, MINN.

We[1] first gave ephedrine sulphate for narcolepsy, Sept. 9, 1930. Now that practically one year has elapsed, it seems desirable to analyze the results of this form of treatment in order to determine, so far as possible, its value. Priority in the use of ephedrine belongs to Janota[2] and Skala,[3] who reported its use in the treatment of narcolepsy at the meeting, June 21, 1930, of the Neurological Society of Prague. Although the report was exceedingly brief, it is evident that these authors obtained favorable results. At the time we first used the drug we had no knowledge of its previous use, since the proceedings of the meeting at Prague were published only in the October number of the *Revue neurologique,* which was received in the United States of America about November 23.

Narcolepsy is characterized by attacks of irresistible sleep, without apparent cause, and in most instances by spells of weakness on emotional stress, particularly on laughing. The latter symptom is often referred to as cataplexy. In addition, these patients frequently gain in weight and may suffer from hypnagogic hallucinations, transient attacks of diplopia, and disturbed nocturnal sleep.

RESULTS IN CASES NOT TREATED WITH EPHEDRINE

In order to estimate the value of any method of treatment, it is necessary to have an accurate concept of the disease in cases in which that treatment has not been used. Accordingly, patients suffering from narcolepsy, who had been examined between Jan. 1, 1919, and

[3] Skala, M., in discussion on Pelnar: Narcolepsy avec catalepsie, Rev. neurol. **2:** 428 (Oct.) 1930.

Sept. 1, 1930, were written letters of inquiry. Information was obtained in sixty-seven cases.

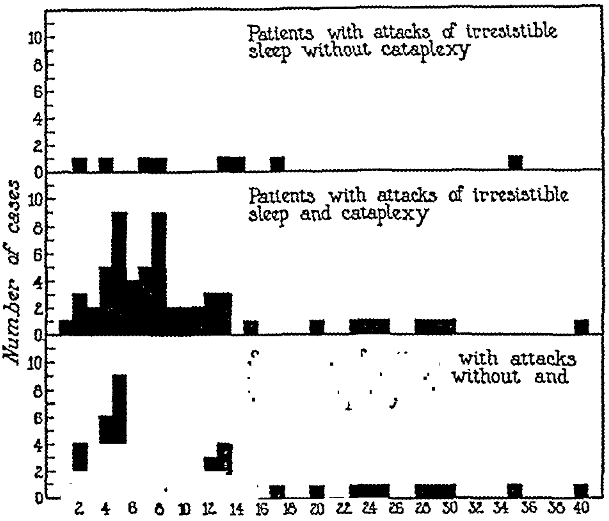
The accompanying chart shows the duration of symptoms at the time of reply to the letter of inquiry, or at the time of death. It also shows the duration of symptoms of the fifty-nine patients who had somnolent attacks and cataplectic seizures, and of the eight who had attacks of irresistible sleep only. It will be seen that the majority of the cases were of four to eight years' duration at the time of reply to the inquiry. One of the patients was subjected only to somnolent attacks for seventeen years, and one for thirty-five years. In one case cataplectic seizures developed after the patient had had somnolent attacks for sixteen years.

Four patients died. One of them was a man, aged 39, who had had somnolent and cataplectic attacks for four years and who died suddenly a few days after he returned home. He had received treatment by roentgen rays over three fields: a frontal, a right temporal and a left temporal. The dose used was about three-fourths erythema dose on the surface, and, by cross-fire, should have produced approximately 60 per cent of the surface dose in the region of the floor of the third ventricle. Although it is well known that the hypothalamic region is very resistant to irradiation, it is conceivable that some latent process may have been activated to the point at which it could have produced death. Such an assumption, however, would be purely speculative. Seven other patients suffering from narcolepsy, who were similarly treated, did not sustain any untoward symptoms attributable to this form of treatment. Another one of those who died was a woman, aged 42, who had had attacks of irresistible sleep and cataplexy for thirteen years and who died from pelvic infection several months after returning home. A third death was that of a man, aged 46, who had somnolent attacks only, and who died following an illness of a few days, one year after his visit to the clinic. The somnolent attacks had become more frequent and prolonged. This patient's blood gave a positive Wassermann reaction; the cerebrospinal fluid was negative in detail. The fourth patient of those who died was a man, aged 43, who had had only somnolent attacks for six months at the time of admission. He died at home one year later, three and a half hours after tonsillectomy under anesthesia with cocaine. Careful anatomic examination of the brain was not made in any of these cases.

Table 1.—*Course of Narcolepsy (Patients not Given Ephedrine)*

Patients traced		67
Improved		30
Markedly	4	
Moderately	4	
Slightly	8	
Very slightly (one without cataplexy)	14	
Same (four without cataplexy)		25
Worse (one without cataplexy)		8
Died (two without cataplexy)		4

Table 1 represents an attempt to estimate the progress or course of the disease as it affected the sixty-seven patients who were traced. Of the four patients who were markedly improved, one, a man aged 46, had had disturbed nocturnal sleep, with many dreams, for twenty years. In the last three years prior to his admission, however, the dreams had become horrible. For the same period of twenty years he had been subject to attacks of irresistible sleep. This tendency had become worse in the last ten years. Four years before his admission to the clinic, and sixteen years after the onset of diurnal somnolence and disturbed nocturnal sleep, he had begun to have cataplectic seizures. From a letter received four years after his visit to the clinic, it was learned that he was much better. In addition, he wrote: "I still fall asleep at times but do not collapse as formerly." The second of these four patients, a youth aged 17, who, eleven months before admission, began to have attacks of irresistible sleep, and spells of weakness on laughing, stated that his attacks of irresistible sleep had ceased five months after the onset, following lumbar puncture and withdrawal of cerebrospinal fluid. The cataplectic attacks had persisted. One and a half years after his admission the patient wrote: "I am entirely well except for slight spells of weakness." The reaction of this patient to drainage of spinal fluid resembles those of the two patients described by Lhermitte.[4] One patient, who had shown moderate improvement, had suffered from the syndrome for thirty years. It is our opinion, confirmed in several instances by voluntary statements of patients, that apparent improvement is often the result of adjustment or adaptation to the syndrome rather than to change in fundamental symptoms. The remaining two cases in which there was marked improvement will not be commented on.



Duration of symptoms at time of inquiry (years).

Of the twenty-five patients who reported that their condition was the same as when they were seen at the clinic, eleven had had the condition for ten or more years; in four cases symptoms had persisted for twenty-five, twenty-nine, thirty-five and forty years, respectively. Of the eight patients who reported that their symptoms were worse, there was one whose symptoms dated back twenty years. It is apparent that narcolepsy runs a chronic course without any marked tendency to self limitation.

RESULTS IN CASES TREATED BY EPHEDRINE

Follow-Up Data on Cases Previously Reported.—Our[5] results with the use of ephedrine sulphate in the treatment of six patients with narcolepsy, up to December, 1930, have been published. An effort has been made to keep in touch with these patients. The first patient, a man aged 20, apparently was completely relieved for several months. Subsequently the drug became less and less effective and his symptoms became more severe. Efforts to adjust the dosage were unsuccessful. Anterior lobe of the hypophysis was given for three weeks without success. In the second case, that of a boy aged 11 years, the medicine continues to be effective in controlling symptoms at the end of nine months. A woman, aged 43, whose case was the third, continues to show marked improvement at the end of nine months. She has an occasional mild cataplectic seizure. This patient usually takes 50 mg. of ephedrine but once daily, at 10 a. m. In the fourth case, that of a man aged 25, there is improvement but not complete relief from taking 75 mg. of ephedrine three times a day. The hypnagogic hallucinations now trouble this patient only when ephedrine is not taken sufficiently late in the evening or when he is excessively fatigued. This man's work necessitates his being active until 2 a. m. The fifth case was that of a woman, aged 57, who was completely relieved with small doses. Six months after she had left the clinic she informed us that she had discontinued treatment in spite of symptomatic relief, because no curative effect was to be expected. The sixth patient, a woman, aged 42, who had had symptoms for twenty-eight years, has been completely relieved for nine months. This patient lives nearby and has been carefully observed. When the use of ephedrine was stopped in April, 1931, for one week, the symptoms of somnolence and cataplexy returned.

* Patients treated by Skala with ephedrine, hypodermically.

Data on New Cases.—Since submission of our second report for publication, we have treated eighteen additional cases of typical narcolepsy. The results in these eighteen cases are included in table 2. In four of these cases, we have learned that complete relief persists after periods of five months in one, four months in two, and three weeks in one. In six other cases, complete relief was obtained during the period of observation in Rochester, which varied from three to five days; follow-up data are not yet available. One of these six patients did not have cataplexy. Another of these six patients, aged 33, who had had increasingly severe symptoms of Raynaud's disease, involving chiefly the hands, had submitted to cervicothoracic sympathetic ganglionectomy. The symptoms of Raynaud's disease in the upper extremities were relieved, but the attacks of irresistible sleep and of cataplexy to which the patient had been subject for four years before operation were unaffected. The remaining four of these six patients do not require comment.

Marked improvement has been obtained in five cases in which treatment has been given since publication of our second report; in four, this has continued for periods of five months, three months, one month and two weeks, respectively. One of these four patients sleeps occasionally but was completely relieved of cataplexy during a period of three months. The patient who has continued to have relief for a period of one month, another of the four, has never had cataplexy. There is nothing of especial interest in the other two of these four cases. One patient, of the five who were markedly improved, treated recently, has also been relieved of hypnagogic hallucinations. The fifth patient of these five did not present anything of especial interest.

Moderate relief was obtained in two instances. Temporary relief was obtained in one instance (ephedrine seemed to lose its therapeutic effect after the first few weeks of its administration). By "temporary relief" we mean that we have evidence that there was improvement for a time and that this improvement came to an end; it is possible, of course, that in some of the other cases which we have observed for only a short time improvement may eventually prove to be only temporary.

Fifteen patients who had been given a diagnosis of narcolepsy in the clinic were treated at home under the supervision of their family physicians. Five of these patients appear to have been completely relieved. Four of the five patients continued to be relieved after one, two, three and four months, respectively. The remaining patient in this group of five who did not have cataplexy stopped treatment after a short period, owing to unpleasant symptoms attributable to the drug. Seven patients were markedly relieved over periods varying from two to four months. The nocturnal sleep of one of the patients of this group of seven had been disturbed; after the beginning of treatment, sleep became restful and natural. In another case of the seven the spells of weakness have been completely relieved and somnolence is lessened. There is nothing of particular interest in the remaining five cases of this group of seven. Twelve patients of this group of fifteen have been mentioned; three remain. One patient of these three seemed to have been moderately relieved of attacks of irresistible sleep and completely relieved of spontaneous cataplectic attacks. Desiccated thyroid gland was then added, with almost complete relief from symptoms. About two months later, this combined treatment apparently was failing to control the symptoms as well as before. In another instance of the three, the physician reported that treatment with ephedrine had been begun with "uncertain results." Another patient of the three, a boy aged 10 years, not subject to cataplectic seizures, in whose case a diagnosis of questionable encephalitis had been made, and who had been somewhat relieved by taking the leaf of stramonium, was reported to be worse while taking ephedrine and is classified in our data as a failure.

The results of treatment of seven additional cases of narcolepsy were made available to us through the courtesy of the attending physicians. In three instances, complete relief was obtained; in one instance, marked improvement, and in three instances, moderate improvement. One of the three patients of those who were moderately improved previously was unable to work at his occupation of traveling salesman; he was almost completely relieved at first. When he returned to work, his symptoms recurred to a considerable extent but subsequently became ameliorated. Another of the patients who was moderately improved continued to have attacks of sleep but was completely relieved of the spells of weakness. In addition, he slept better at night, was wider awake in the intervals between his attacks of sleep, and felt better generally. The condition of the third patient of these three does not require special comment.

Data on Cases Reported in the Literature by Other Authors.—The first patient ever treated by ephedrine was probably Janota's. It would seem that the patient was markedly improved. At the suggestion of Janota, Skala treated two patients with ephedrine, administering the drug hypodermically. The attacks of irresistible sleep appear to have been markedly diminished; the cataplectic seizures were unaffected in the first case and somewhat diminished in severity in the second; Grün[6] has recently reported the results of treatment with ephedrine in a typical case of narcolepsy. The patient, a man aged 60, was given 50 mg. of ephedrine sulphate thrice daily over a period of eight weeks. The patient appeared to derive some slight benefit during the first few days only. This case has been classified by us as a failure. Grün suggested that narcolepsy may be due to a variety of pathologic processes, some of which are uninfluenced by treatment with ephedrine.

COMMENT

As a rule the patients were given ephedrine sulphate in two doses of 25 mg. each, before breakfast and before the noonday meal. In certain instances this dosage sufficed. If it did not suffice, 25 mg. was given as a third dose at 4:30 p. m. The choice of this hour was made in order to avert disturbance of nocturnal sleep. In a considerable number of instances it was necessary to increase the morning, the noon and, in a few instances, even the afternoon dose to 50 mg. In but one instance was 75 mg. given thrice daily. It is to be noted that a few patients have been able to take as little as from 20 to 25 mg. once or twice daily, with almost complete relief from symptoms.

Numerous determinations of the blood pressure have been made. Aside from a slight rise from thirty to sixty minutes after administration, no effect on the systolic or the diastolic blood pressure was recorded. Two patients had essential hypertension; their pressures were not affected by the administration of ephedrine.

One patient who was completely relieved by ephedrine suffered a complete relapse while taking liquid petrolatum for the relief of constipation. When use of the oil was discontinued, he was again completely relieved. This appears to afford clinical corroboration of the fact mentioned by Chen and Schmidt[7] that ephedrine sulphate is not soluble in liquid petrolatum and it may explain certain cases in which the treatment has failed. This patient and another under observation by the same physician have been relieved for eight months.

SUMMARY

A survey was made of information obtained concerning sixty-seven patients who were given a diagnosis of narcolepsy in the clinic and who had not been treated with ephedrine. The duration of the disorder ranged from one to forty years. No patient had recovered completely. Thirty patients wrote that they had improved. In fourteen instances, however, the improvement was very slight. Twenty-five patients reported that they were the same, and eight that they were worse. Four patients had died.

Fifty patients have been treated with ephedrine, including those treated by others as well as those treated by us. To the best of our knowledge, the treatment was a total failure in two instances. Two patients, who at first were improved, no longer appear to receive any effect from the drug. Eight patients have been moderately improved symptomatically. Seventeen patients have made marked symptomatic improvement, and twenty have been completely relieved symptomatically. In the two groups mentioned in the preceding sentence, symptomatic relief continues as follows: in four patients after nine months, in two after eight months, in two patients after five months, in three patients after four months, in six after three months, and in four after two months.

BISMUTH SUBNITRATE IN THE TREATMENT OF ARTERIOLAR (ESSENTIAL) HYPERTENSION *

DAVID AYMAN, M.D.
BOSTON

Excellent therapeutic results following the use of bismuth subnitrate in 200 patients with arteriolar (essential) hypertension were recently reported by Stieglitz.[1] In the present paper I report unsuccessful results with the drug after its long administration to a small though well studied group of patients with arteriolar hypertension.

THE RATIONALE FOR USING BISMUTH SUBNITRATE IN ARTERIOLAR HYPERTENSION

Stieglitz was prompted to use bismuth subnitrate in arteriolar hypertension after "observation of three cases of nitrate poisoning resulting from the liberal use of bismuth subnitrate in severe diarrheas,"[2] together with the observation that "hypotension may occur in normal individuals from excessive administration of bismuth subnitrate for diarrhea."[1]

It should, of course, be borne in mind that low blood pressure occurs in many cases of severe diarrhea, chiefly as a result of the great loss of fluid through the bowel with consequent reduction of blood volume.[3] The administration of bismuth subnitrate to these patients with diarrhea may therefore have been coincidental to, rather than the cause of, the hypotension. Even in the hypertensive patient, severe diarrhea may lower the blood pressure.[4]

Stieglitz[5] believes that the nitrate radical of bismuth subnitrate is changed into nitrites by bacteria in the intestine, that the nitrites are there absorbed into the blood stream, producing the hypotensive effect of the nitrites, and that finally some of the nitrites appear in the urine, giving slightly positive nitrite tests. The presence of slightly positive nitrite tests of the urine, however, does not lend great support to this conception, because positive nitrite tests of the urine, especially

During period F, while bismuth subnitrate was taken by the patient for six months, the blood pressure was not affected to the slightest degree demonstrable. On the other hand, during period C the blood pressure was lowered by the thiocyanates; during period D it was lowered by frequent visits; during period E it was lowered by frequent visits plus pink-colored water, and at all times it was lowered by sitting rest periods. A similar study of the other fourteen cases showed absolutely no demonstrable effect of the bismuth subnitrate on the blood pressure.

It must be borne in mind that although the accompanying chart or any similar chart apparently presents the blood pressure readings of a patient during three and a half years of observation, it in reality only shows the blood pressure readings taken during each of sixty-six visits to the clinic, a very small part of the three and a half years, for the straight lines connecting each visit must be arbitrary, merely showing apparent tendencies of the blood pressure level.

There was no effect on the symptoms other than what might be attributed to the pure suggestion supplied with any therapy. Seven of the patients were symptomless at the start of the study.

"UNTOWARD" SYMPTOMS DURING THERAPY

During the course of treatment, three of the fifteen patients manifested "untoward" symptoms which may have been purely coincidental to, rather than caused by, the administration of the drug. Stieglitz has reported no reactions in his studies. In case 5 of the present study the patient stated that on the seventy-seventh day of treatment severe pain in the left upper quadrant of the abdomen appeared, which lasted for one hour, during which time she was unable to urinate. This disappeared and did not recur despite continuation of the drug. In case 6, on the hundred and thirty-ninth day of treatment the patient complained of rising to urinate two or three times a night during the preceding week, of difficulty in urinating, of pain after urination and of the appearance of blood in the urine. There was no fever. A catheter specimen of urine contained 80 erythrocytes and 10 leukocytes to the high-power field, but no albumin or casts. Cystoscopic examination disclosed "diffuse congestion of the entire bladder mucosa." Pyelograms of the kidney did not reveal abnormality. The symptoms disappeared one week after the bismuth subnitrate was discontinued. In case 14 the patient complained of anorexia, constipation, marked restlessness and insomnia on the second day after taking the drug. He appeared very upset and felt certain that some mistake had been made in dispensing the drug. However, after he was given a new package of the drug, the same symptoms developed and he refused to take any more of it. In this case it was possible that the symptoms were of purely psychic origin, because previous distressing symptoms from treatment with thiocyanate may have caused him to fear any further therapy.

Only three patients (cases 3, 5 and 6) found that the bowels were slightly more constipated while they were taking the drug than before treatment.

SUMMARY OF RESULTS

Bismuth subnitrate given in doses of 2 Gm. (30 grains) daily for periods of from three to nine months had no demonstrable effect on the blood pressure of fifteen carefully studied and controlled patients with arteriolar (essential) hypertension.

LIPODYSTROPHY

A REPORT OF SIX CASES IN CHILDREN *

A. H. PARMELEE, M.D.
OAK PARK, ILL.

Lipodystrophy is defined by Coates[1] as a "disease especially liable to affect children 5 to 8 years of age, in which characteristically there is a loss of subcutaneous fat of the face, neck, thorax, arms and abdomen, without assignable cause or gross symptoms of ill health. In association with this, there is in addition, in females, an increase of subcutaneous fat below the iliac crests."

Like many other diseases, it remained obscure until attention had been sufficiently attracted to it by case reports in the medical periodicals. Thus in 1917, J. Parkes Weber[2] summarized twenty-seven cases including his own reported to that date, while in 1924, Reuben, Zamkin and Fox[3] found sixty cases recorded and Coates in 1925 summarizes sixty-three cases. In 1927, eight case reports were found and there have been at least five cases reported in children under 14 years since 1927. Barraquer reported the first authentic case in 1906. Campbell described a case in 1907. However, Osler had records of a case seen by him in 1895, and permitted Weber[4] to report it along with his own cases in 1917. In 1911, Arthur Simons reported a case he had studied carefully and gave the name lipodystrophia progressiva to the disease. The first case reported in this country was by Herrmann[5] in 1916.

The outstanding features are the thin, almost cadaverous looking face and upper part of the trunk, while the lower part of the trunk and the legs look either normally or better than normally well nourished. Also, there is no loss of muscular power nor disturbance of sensation over the parts affected, and the individual is active and strong and well in every other respect. Although the face often appears pale, no anemia can be demonstrated. The onset is usually in young childhood. Thirty-nine of the sixty-three cases recorded by Coates had their onset before or in the eighth year, the youngest patient being two years of age. Forty-six patients were 10 years of age or younger. The age was not recorded in eight cases, so it is fair to assume that at least 82 per cent were 10 years of age or younger when symptoms began, and the great majority of these were between 6 and 8 years.

In this series also there were forty-two females and twenty-one males, or a preponderance among females of 2 to 1. It was at first thought to be a disease peculiar to females, but in 1916 Gertsmann[6] and again in the same year Gerhartz[7] reported each a case in a male. Since then, numerous cases have been reported and the preponderance of female cases is getting steadily less.

Four of the cases reported below came to the pediatric ward of the Presbyterian Hospital on the service of Dr. C. G. Grulee, and I am indebted to him for the privilege of studying and reporting these cases.

REPORT OF CASES

CASE 1.—*History.*—M. O., a girl, aged 10 years, first consulted me, Oct. 16, 1925. Her complaint was that her face was thin and pale. The parents first noticed that she was getting thin in the face and neck a few months after the removal of her tonsils four years before; i. e., when the child was 6 years old. This condition had become gradually more marked until within the last year it seemed to have become stationary. There was no other complaint; her appetite was good, she played normally and vigorously and did not tire easily, and she slept well, did well in school, and in every way acted like a healthy normal child. She had gained 7 pounds (3.2 Kg.) during the past year.

She was the second child of healthy parents. The mother's pregnancy was normal, as was her labor. The child's birth weight was 8¼ pounds (4 Kg.). She was breast fed for eight months, did well through infancy and developed normally as to teething, walking, talking, and so on. She had whooping cough at the age of 3 years, chickenpox at 4 years, measles at 4 years, and mumps at 8 years. When she was about 3 years old, she had influenza and had frequent earaches but never a discharging ear; she had had no earache since the tonsillectomy at the age of 6 years. In the family history there was nothing of significance.

Examination.—When seen before removing her clothes, she gave the impression of a sick child; the face was very thin, the cheeks were sunken, there were wrinkles about the mouth and chin, the cheek bones were prominent, the eyes were sunken, and there was a peculiar pallor that was ghastly When the clothes were removed she was seen to have a well nourished and perfectly normal appearing body from the clavicles down. The abdomen, hips and legs were especially well covered with fat but not abnormally so. The thickness of the subcutaneous fat on the chest, arms and abdomen seemed normal but was entirely lacking on the neck, face and scalp. A thorough physical examination revealed nothing abnormal except as already described.

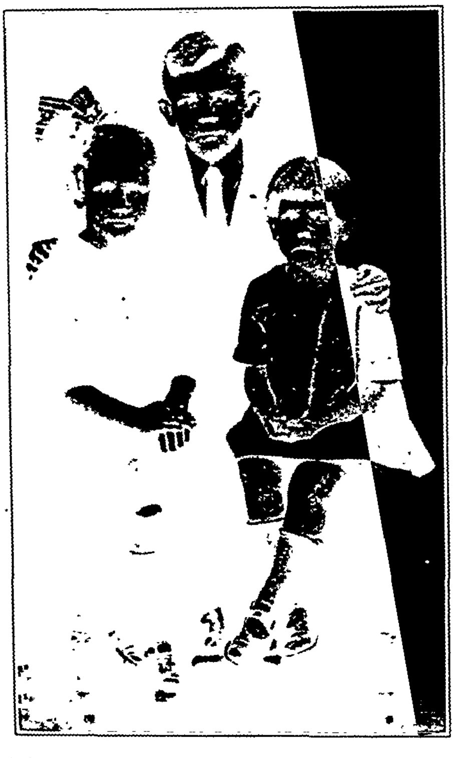

Fig. 1 (case 3).—Patient (the child on the left) at the age of 7.

At the Presbyterian Hospital, our investigations revealed the following data: Pirquet reaction, negative; blood Wassermann reaction, negative; urine, entirely normal; blood count showed: red blood cells, 4,500,000; white blood cells, 12,000; polymorphonuclear neutrophils, 67 per cent; eosinophils, 2; basophils, 1; small mononuclears, 23; large mononuclears, 4; no abnormal cells; hemoglobin, 85 per cent. Chemical analysis of the blood revealed: urea, 22; uric acid, 2.4; creatinine, 1.15; total nonprotein nitrogen, 24; blood sugar, 102; blood calcium, 10.8. The basal metabolic rate was —7. A roentgenogram of the skull showed a normal sella. Neurologic examination by Dr. Peter Bassoe revealed nothing pertaining to the nervous system and his comment was: "The striking feature is the deficiency of subcutaneous fat in the face and neck, while the muscles are strong."

Case 2.—*History.*—J. F., a girl, aged 7½ years, entered the Presbyterian Hospital, Feb. 26, 1926, in the service of Dr. Grulee, with the following complaint: thin face, nervousness, and failure to gain in weight. For the past three and one-half years, i. e., since the child was 4 years old, the mother had noticed that, in spite of a good appetite, plenty of good food and plenty of sleep, the child appeared to become gradually thinner and thinner. This condition the mother dated back to a severe attack of tonsillitis at the age of 4 years, since which time the patient had had repeated attacks of tonsillitis until nine months previously, when the tonsils were removed. She was very active, played vigorously and seemed well but tired rather easily. In school she received good grades.

She was the second child of healthy parents. She had one older sister and one younger sister, both living and well. The mother had had several miscarriages since the last child. The patient was born six weeks prematurely and weighed 4¼ pounds (2 Kg.). She was breast fed for four months and did well through infancy, developing normally in every way. Until she was 4 years old she appeared normal. She had whooping cough at 1½ years, chickenpox at 3 years and follicular tonsillitis at 4 years. The family history was without significance except that the mother's father died of tuberculosis, as did also a half sister.

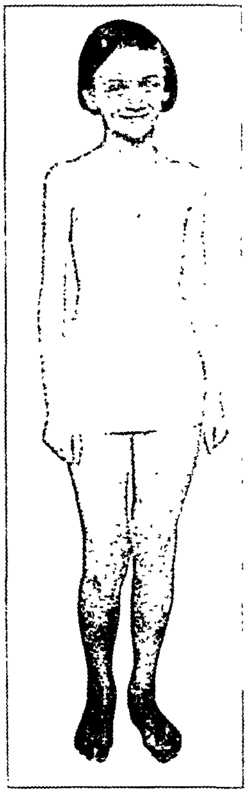

Fig. 2 (case 3).—Appearance at age of 10.

Examination.—The child did not appear ill but looked extremely thin in the face and upper part of the trunk, while the rest of her body was moderately well nourished. The contrast was striking. There were wrinkles about the mouth, and the cheeks were sunken. There seemed to be no subcutaneous fat in the face, neck, upper part of the chest and upper arms, but the abdomen and legs seemed to be normally padded. Thorough physical examination did not reveal anything abnormal except a systolic murmur heard best over the heart apex. A roentgenogram of the chest showed enlargement of the tracheobronchial lymph glands. There were no neurologic observations, and muscle power seemed everywhere to be normal. The temperature ranged between 98 and 99.4 during the four days she was in the hospital, and the pulse rate was from 80 to 100. The Pirquet reaction was positive; the Wassermann reaction of the blood was negative; the urine was entirely normal. The blood count gave the following results: red blood cells, 5,580,000; white blood cells, 10,300; polymorphonuclear neutrophils, 40 per cent; eosinophils, 3; small mononuclears, 20; large mononuclears, 37. No abnormal cells were seen. The hemoglobin was 99 per cent. Chemical analysis of the blood showed: urea nitrogen, 17.7; uric acid, 3.08; creatinine, 1.32; total nonprotein nitrogen, 37.2; blood sugar, 93; blood chlorides, 495. The basal metabolic rate was —12.

Case 3.—*History.*—J. P., a girl, aged 10 years, entered the Presbyterian Hospital, March 4, 1926, in the service of Dr. Grulee. The only complaint was thinness of the face and chest. For the past two and one-half years the mother had noticed that the child was getting thin, especially in the face. This was first noticed shortly after a tonsillectomy. In spite of a good appetite and gradual gain in weight, the thinness of the face gradually became more marked. The patient had always seemed to feel well, played actively, slept well and got along well with other children, except that lately they had been poking fun at her on account of her thin face, which looked so old and haggard. She was bright and did good work in school.

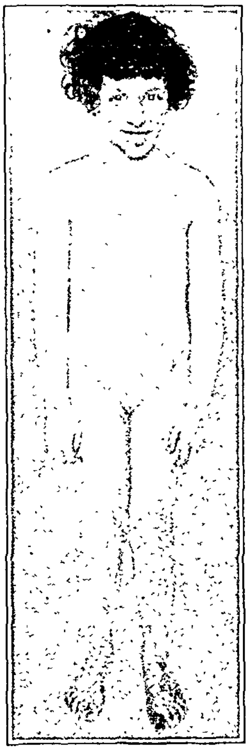

Fig. 3 (case 4).—Patient at age of 8.

She was the second child of healthy parents, born normally, at full term; her birth weight was 8½ pounds (3.8 Kg.). She was breast fed until 1 year old, and developed normally in every way. There were two other children, one aged 12 years and one 8 years, both in good health. At 2½ years she had an attack of bronchitis, at 3 years chickenpox, at 4 years measles and mumps, and at 7 years tonsillitis. In the family history there was nothing of significance.

Examination.—There was apparent absence of subcutaneous fat in the face, while the markings and actions of all the muscles were present. The arms and trunk had an emaciated appearance, while the muscles were well preserved. The abdominal wall was about normal in appearance and there seemed to be a fair amount of subcutaneous fat in the gluteal region and the lower extremities. There was perhaps a slight excess of fat in the upper part of the thighs. The muscle power seemed to be everywhere normal and the reflexes were all normal. Careful examination did not reveal anything unusual or abnormal further than already described. The Pirquet reaction was positive; the blood Wassermann reaction was negative; the urine was entirely normal. The blood count showed: red blood cells, 5,630,000; white blood cells, 20,200; polymorphonuclear neutrophils, 77 per cent; basophils, 1; small mononuclears, 11; large mononuclears, 21. No abnormal cells were noted. The hemoglobin was 99 per cent. Chemical analysis of the blood revealed urea nitrogen, 18.74; uric acid, 3.55; creatinine, 1.32; total nonprotein nitrogen, 37.72; blood calcium, 10.42. The basal metabolic rate was —7. A roentgenogram showed a normal sella.

Case 4.—*History.*—R. K., a girl, aged 8 years, entered the Presbyterian Hospital, in the service of Dr. Grulee, April 25, 1927. The only complaint was that she was thin in the face. Until two years ago, the mother stated, she was normal in appearance, but since then her face had been getting gradually thinner and more wrinkled; now the neck and upper part of the chest was also becoming thin. Her appetite was fair and she felt well and was active. There had been no loss of weight.

She was the ninth child, and she had been born at full term, after prolonged but spontaneous delivery. The birth weight is not known. She was breast fed for one year. She developed normally. At 1 year she had smallpox and at 5½ years measles; she has had frequent colds and has had a chronic suppurative otitis media for two years. Tonsillectomy was performed at 7 years. The father died at the age of 40 of influenza. The mother, aged 49, was living and well. Six other children were living and well. Two died of pneumonia following measles.

Examination.—The appearance was striking, for the face and neck and upper portion of the chest were very thin, and the remainder of the body seemed well nourished. The cheeks were sunken and the cheek bones prominent. When she smiled there were wrinkles about the mouth and on the chin. Added to this the face was badly scarred as the result of smallpox. The muscles of the face and neck and chest stood out plainly and seemed normally strong. The lower part of the trunk and the legs seemed well padded with fat. The deep and superficial reflexes were all normal, and there was no disturbance of cutaneous sensations. Further examination showed purulent discharge from the right ear and slight cervical adenopathy. The spleen was palpable. There were no other observations of significance.

A roentgenogram of the chest showed enlarged tracheobronchial glands. The Pirquet reaction was very strongly positive; the blood Wassermann reaction was negative; the urine was entirely normal. The blood count showed: red blood cells, 5,040,000; white blood cells, 8,200; neutrophils, 68 per cent; small mononuclears, 24; large mononuclears, 8. No abnormal cells were noted. The hemoglobin was 88 per cent. Chemical analysis of the blood gave the following results: urea nitrogen, 10.9; uric acid, 4.1; creatinine, 1.3; total nonprotein nitrogen, 31.4; cholesterol, 159.2. The basal metabolic rate was —5. The blood calcium was 10.21; the blood sugar, 86.9; carbon dioxide, 52.2 per cent by volume.

Case 5.—*History.*—W. Van H., a girl, aged 9¾ years, entered the Presbyterian Hospital, Nov. 16, 1927, in the service of Dr. Grulee. She had been visiting the Central Free Dispensary because of some abdominal pain, and the mother said that she was gaining in weight slowly and was worried about her face looking so very thin. The only other complaint was that she seemed to tire easily. In every other way she seemed to be normal, had a good appetite, played vigorously, slept well, and got on well in school.

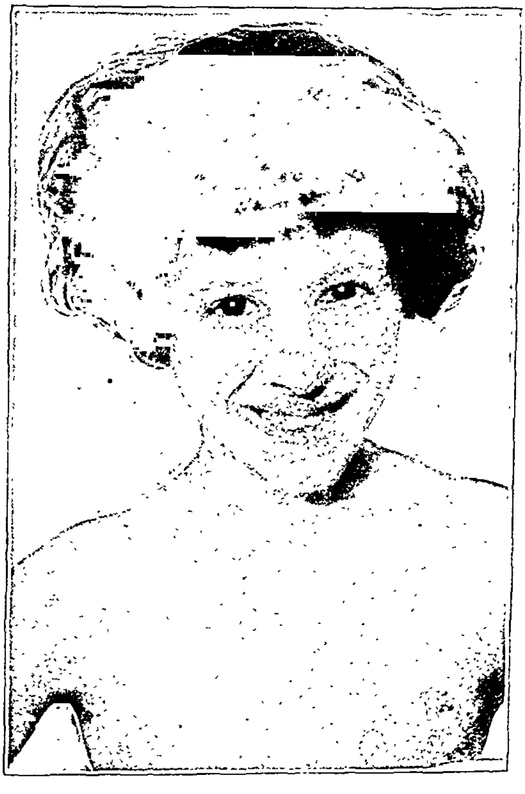

Fig. 4 (case 4).—Appearance at age of 8. Note the wrinkles about the mouth.

For the past two years her face had been getting gradually thinner and thinner. The mother and father were well and had four other children, all of whom were well. One child had died at the age of 4 days from a congenital atresia of the esophagus and a congenital heart defect. The mother was well while carrying the present patient and had a normal labor, and the infant was normal at birth. She was breast fed for three months, did well during infancy and developed normally in every way. At 9 months she had scarlet fever and at 7 years measles and whooping cough. Her tonsils were removed at 8 years. She had had some head colds but no other acute illnesses. In the family history there was nothing significant.

Examination.—The striking feature was the very thin face in contrast to the fairly plump and well nourished trunk and lower extremities. The face looked sallow and wrinkled and old; the cheeks were sunken, there were wrinkles about the mouth and eyes, which showed up strikingly when she smiled. Only a little subcutaneous fat could be felt on the face and neck and only a little more over the upper part of the chest and arms, but from the costal margins down there seemed to be a normal amount of it. The muscles of the face were normal in power; the jaw reflex was present and normal. The same was true of the muscles of the arms and thorax. The deep and superficial reflexes elsewhere were normal. The thyroid gland was but slightly enlarged. Further careful examination did not reveal any abnormalities or signs of disease.

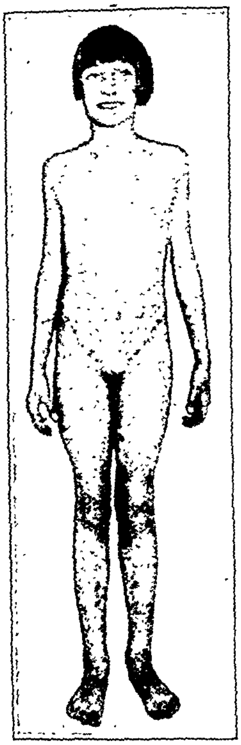

Fig. 5 (case 5).—Patient at the age of 9¾ years.

The Pirquet and the blood Wassermann reactions were both negative. The blood count gave the following results: red blood cells, 4,800,000; white blood cells, 10,900; neutrophils, 60 per cent; small mononuclears, 38; large mononuclears, 2. No abnormal cells were noted. The hemoglobin was 80 per cent. The urine was entirely normal. Chemical analysis of the blood revealed urea nitrogen, 10.7; uric acid, 3.8; creatinine, 1.4; total nonprotein nitrogen, 30.2; blood phosphorus, 4.06; blood calcium, 10.7; blood cholesterol, 142.2; blood sugar, 90.9; blood chlorides, 480; carbon dioxide, 56 per cent by volume. A roentgenogram of the long bones did not show any evidence of disturbance of bone growth. The basal metabolic rate was —19.

Case 6.—*History.*—R. S., a girl, aged 10½ years, was brought to me, May 3, 1928, with the complaint that for the last four years she had been thin and that in spite of a good appetite she was becoming thinner. There were no other complaints, except that she had vague pains in the stomach at times.

She was the second child of healthy parents. The mother's pregnancy was normal, as was her labor. The infant seemed normal at birth and weighed 8 pounds (3.6 Kg.). She was normal through infancy, developing normally and having no illness. At 3 years she had a very severe attack of pharyngeal diphtheria, and the mother thought that she had never seemed quite as sturdy since then. Her tonsils and adenoids were removed when she was 4; at 5 she had measles and whooping cough.

Examination.—The face was thin and sallow, with wrinkles about the mouth. There seemed to be a complete absence of subcutaneous fat in the face, neck, upper part of the thorax to just below the clavicles, and to about the middle of the upper arms. The remainder of the body seemed to be quite normally padded with fat. There was no disturbance of muscular power; the reflexes were all normal, and there was no disturbance of the sensory nerves. All other physical conditions were entirely normal. Her weight was 66¾ pounds (30.2 Kg.) and her height 53½ inches (136 cm.).

Laboratory observations at the Presbyterian Hospital were as follows: blood: hemoglobin, 75 per cent; red blood cells, 4,570,000; white blood cells, 7,500; differential count: neutrophils, 53 per cent; small mononuclears, 39; large mononuclears, 3; eosinophils, 5. Urinalysis was negative. The stools were normal. The basal metabolic rate was —12 (Du Bois). The Pirquet and the Wassermann reactions were negative.

Absolutely no clue to the etiology of this strange disease is as yet at hand, though many writers have indulged in interesting speculations. Some, as would be expected, strongly favor some endocrine disturbance. Feer, for instance, inclines toward a thyroid dysfunction as the most plausible cause. To others [8] the distribution of the fat atrophy stands in the way of accepting the endocrine theory. Simons refers to it as "a sister of the muscular dystrophies" and considers it most likely a trophoneurosis. Weber suggests a disturbance of the vegetative nervous system with redistribution of fat in the subcutaneous tissues analogous to that of pigment in the skin in vitiligo.

The relationship of one case to osteogenesis imperfecta suggests a developmental error in the mesenchyme. This idea with variations has been suggested by several. Such diseases as syphilis and tuberculosis seem definitely to have been ruled out.

Klien reported a case in which loss of fat of the face and chest followed a street car accident that had caused a severe head injury. In this case there were several symptoms referable to either vasomotor or endocrine disturbances; i. e., rhinorrhea, polyuria and hypertrichosis. This investigator finds definite evidences of vasomotor disturbances in eleven of the case reports then at hand, and from this suggestion he propounds the following explanation as a possibility:

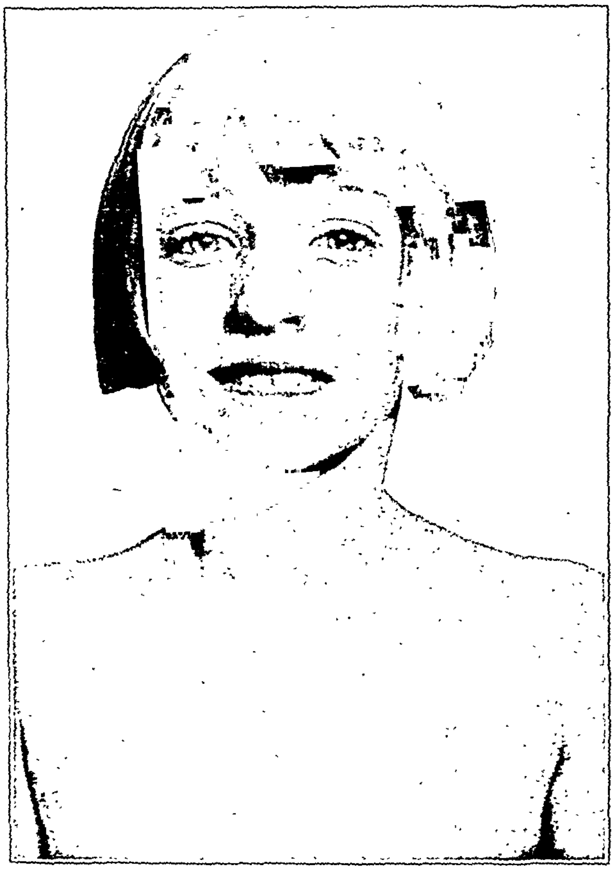

Fig. 6 (case 5).—Patient at age of 9¾ years.

A center controlling fat distribution is assumed to exist in the subthalamic portion of the midbrain, which is intimately connected with the pineal gland through sympathetic nerve fibers. A localization of control for chest. For the past two and one-half years the mother had noticed that the child was getting thin, especially in the face. This was first noticed shortly after a tonsillectomy. In spite of a good appetite and gradual gain in weight, the thinness of the face gradually became more marked. The patient had always seemed to feel well, played actively, slept well and got along well with other children, except that lately they had been poking fun at her on account of her thin face, which looked so old and haggard. She was bright and did good work in school.

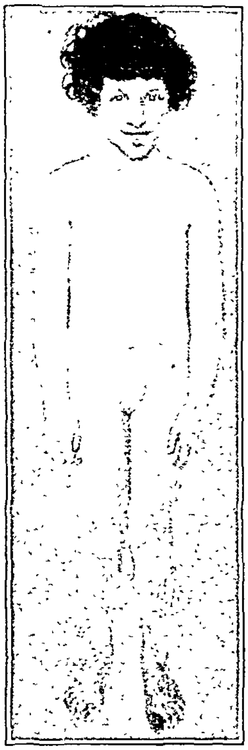

Fig. 3 (case 4).—Patient at age of 8.

She was the second child of healthy parents, born normally, at full term; her birth weight was 8½ pounds (3.8 Kg.). She was breast fed until 1 year old, and developed normally in every way. There were two other children, one aged 12 years and one 8 years, both in good health. At 2½ years she had an attack of bronchitis, at 3 years chickenpox, at 4 years measles and mumps, and at 7 years tonsillitis. In the family history there was nothing of significance.

Examination.—There was apparent absence of subcutaneous fat in the face, while the markings and actions of all the muscles were present. The arms and trunk had an emaciated appearance, while the muscles were well preserved. The abdominal wall was about normal in appearance and there seemed to be a fair amount of subcutaneous fat in the gluteal region and the lower extremities. There was perhaps a slight excess of fat in the upper part of the thighs. The muscle power seemed to be everywhere normal and the reflexes were all normal. Careful examination did not reveal anything unusual or abnormal further than already described. The Pirquet reaction was positive; the blood Wassermann reaction was negative; the urine was entirely normal. The blood count showed: red blood cells, 5,630,000; white blood cells, 20,200; polymorphonuclear neutrophils, 77 per cent; basophils, 1; small mononuclears, 11; large mononuclears, 21. No abnormal cells were noted. The hemoglobin was 99 per cent. Chemical analysis of the blood revealed urea nitrogen, 18.74; uric acid, 3.55; creatinine, 1.32; total nonprotein nitrogen, 37.72; blood calcium, 10.42. The basal metabolic rate was —7. A roentgenogram showed a normal sella.

Case 4.—*History.*—R. K., a girl, aged 8 years, entered the Presbyterian Hospital, in the service of Dr. Grulee, April 25, 1927. The only complaint was that she was thin in the face. Until two years ago, the mother stated, she was normal in appearance, but since then her face had been getting gradually thinner and more wrinkled; now the neck and upper part of the chest was also becoming thin. Her appetite was fair and she felt well and was active. There had been no loss of weight.

She was the ninth child, and she had been born at full term, after prolonged but spontaneous delivery. The birth weight is not known. She was breast fed for one year. She developed normally. At 1 year she had smallpox and at 5½ years measles; she has had frequent colds and has had a chronic suppurative otitis media for two years. Tonsillectomy was performed at 7 years. The father died at the age of 40 of influenza. The mother, aged 49, was living and well. Six other children were living and well. Two died of pneumonia following measles.

Examination.—The appearance was striking, for the face and neck and upper portion of the chest were very thin, and the remainder of the body seemed well nourished. The cheeks were sunken and the cheek bones prominent. When she smiled there were wrinkles about the mouth and on the chin. Added to this the face was badly scarred as the result of smallpox. The muscles of the face and neck and chest stood out plainly and seemed normally strong. The lower part of the trunk and the legs seemed well padded with fat. The deep and superficial reflexes were all normal, and there was no disturbance of cutaneous sensations. Further examination showed purulent discharge from the right ear and slight cervical adenopathy. The spleen was palpable. There were no other observations of significance.

A roentgenogram of the chest showed enlarged tracheobronchial glands. The Pirquet reaction was very strongly positive; the blood Wassermann reaction was negative; the urine was entirely normal. The blood count showed: red blood cells, 5,040,000; white blood cells, 8,200; neutrophils, 68 per cent; small mononuclears, 24; large mononuclears, 8. No abnormal cells were noted. The hemoglobin was 88 per cent. Chemical analysis of the blood gave the following results: urea nitrogen, 10.9; uric acid, 4.1; creatinine, 1.3; total nonprotein nitrogen, 31.4; cholesterol, 159.2. The basal metabolic rate was —5. The blood calcium was 10.21; the blood sugar, 86.9; carbon dioxide, 52.2 per cent by volume.

Case 5.—*History.*—W. Van H., a girl, aged 9¾ years, entered the Presbyterian Hospital, Nov. 16, 1927, in the service of Dr. Grulee. She had been visiting the Central Free Dispensary because of some abdominal pain, and the mother said that she was gaining in weight slowly and was worried about her face looking so very thin. The only other complaint was that she seemed to tire easily. In every other way she seemed to be normal, had a good appetite, played vigorously, slept well, and got on well in school.

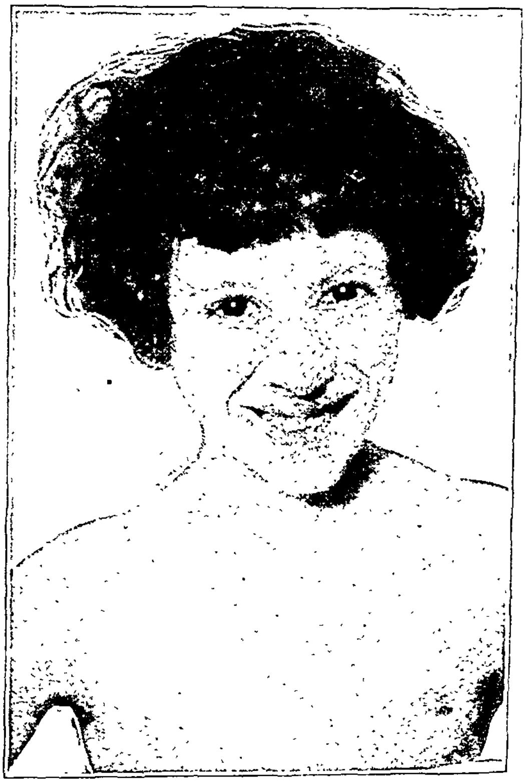

Fig. 4 (case 4).—Appearance at age of 8. Note the wrinkles about the mouth.

For the past two years her face had been getting gradually thinner and thinner. The mother and father were well and had four other children, all of whom were well. One child had died at the age of 4 days from a congenital atresia of the esophagus and a congenital heart defect. The mother was well while carrying the present patient and had a normal labor, and the infant was normal at birth. She was breast fed for three months, did well during infancy and developed normally in every way. At 9 months she had scarlet fever and at 7 years measles and whooping cough. Her tonsils were removed at 8 years. She had had some head colds but no other acute illnesses. In the family history there was nothing significant.

Examination.—The striking feature was the very thin face in contrast to the fairly plump and well nourished trunk and lower extremities. The face looked sallow and wrinkled and old; the cheeks were sunken, there were wrinkles about the mouth and eyes, which showed up strikingly when she smiled. Only a little subcutaneous fat could be felt on the face and neck and only a little more over the upper part of the chest and arms, but from the costal margins down there seemed to be a normal amount of it. The muscles of the face were normal in power; the jaw reflex was present and normal. The same was true of the muscles of the arms and thorax. The deep and superficial reflexes elsewhere were normal. The thyroid gland was but slightly enlarged. Further careful examination did not reveal any abnormalities or signs of disease.

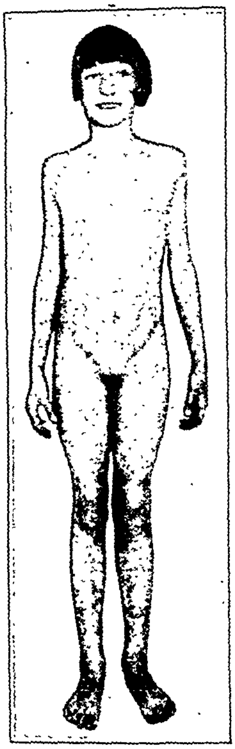

Fig. 5 (case 5).—Patient at the age of 9¾ years.

The Pirquet and the blood Wassermann reactions were both negative. The blood count gave the following results: red blood cells, 4,800,000; white blood cells, 10,900; neutrophils, 60 per cent; small mononuclears, 38; large mononuclears, 2. No abnormal cells were noted. The hemoglobin was 80 per cent. The urine was entirely normal. Chemical analysis of the blood revealed urea nitrogen, 10.7; uric acid, 3.8; creatinine, 1.4; total nonprotein nitrogen, 30.2; blood phosphorus, 4.06; blood calcium, 10.7; blood cholesterol, 142.2; blood sugar, 90.9; blood chlorides, 480; carbon dioxide, 56 per cent by volume. A roentgenogram of the long bones did not show any evidence of disturbance of bone growth. The basal metabolic rate was —19.

CASE 6.—*History.*—R. S., a girl, aged 10½ years, was brought to me, May 3, 1928, with the complaint that for the last four years she had been thin and that in spite of a good appetite she was becoming thinner. There were no other complaints, except that she had vague pains in the stomach at times.

She was the second child of healthy parents. The mother's pregnancy was normal, as was her labor. The infant seemed normal at birth and weighed 8 pounds (3.6 Kg.). She was normal through infancy, developing normally and having no illness. At 3 years she had a very severe attack of pharyngeal diphtheria, and the mother thought that she had never seemed quite as sturdy since then. Her tonsils and adenoids were removed when she was 4; at 5 she had measles and whooping cough.

Examination.—The face was thin and sallow, with wrinkles about the mouth. There seemed to be a complete absence of subcutaneous fat in the face, neck, upper part of the thorax to just below the clavicles, and to about the middle of the upper arms. The remainder of the body seemed to be quite normally padded with fat. There was no disturbance of muscular power; the reflexes were all normal, and there was no disturbance of the sensory nerves. All other physical conditions were entirely normal. Her weight was 66¾ pounds (30.2 Kg.) and her height 53½ inches (136 cm.).

Laboratory observations at the Presbyterian Hospital were as follows: blood: hemoglobin, 75 per cent; red blood cells, 4,570,000; white blood cells, 7,500; differential count: neutrophils, 53 per cent; small mononuclears, 39; large mononuclears, 3; eosinophils, 5. Urinalysis was negative. The stools were normal. The basal metabolic rate was —12 (Du Bois). The Pirquet and the Wassermann reactions were negative.

Absolutely no clue to the etiology of this strange disease is as yet at hand, though many writers have indulged in interesting speculations. Some, as would be expected, strongly favor some endocrine disturbance. Feer, for instance, inclines toward a thyroid dysfunction as the most plausible cause. To others [8] the distribution of the fat atrophy stands in the way of accepting the endocrine theory. Simons refers to it as "a sister of the muscular dystrophies" and considers it most likely a trophoneurosis. Weber suggests a disturbance of the vegetative nervous system with redistribution of fat in the subcutaneous tissues analogous to that of pigment in the skin in vitiligo.

The relationship of one case to osteogenesis imperfecta suggests a developmental error in the mesenchyme. This idea with variations has been suggested by several. Such diseases as syphilis and tuberculosis seem definitely to have been ruled out.

Klien reported a case in which loss of fat of the face and chest followed a street car accident that had caused a severe head injury. In this case there were several symptoms referable to either vasomotor or endocrine disturbances; i. e., rhinorrhea, polyuria and hypertrichosis. This investigator finds definite evidences of vasomotor disturbances in eleven of the case reports then at hand, and from this suggestion he propounds the following explanation as a possibility:

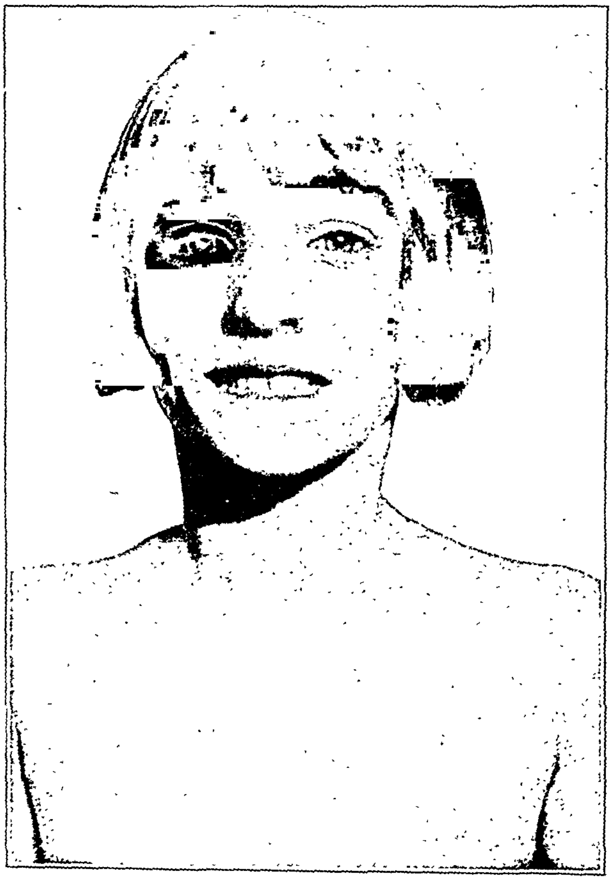

Fig. 6 (case 5).—Patient at age of 9¾ years.

A center controlling fat distribution is assumed to exist in the subthalamic portion of the midbrain, which is intimately connected with the pineal gland through sympathetic nerve fibers. A localization of control for

---

[8] Klien, H.: München. med. Wchnschr. 68: 206-208 (Feb. 18) 1921.

definite segments of the body, either in the center or in the pineal gland would explain the segmental distribution of fat atrophy or hypertrophy, depending on the location of changes in these structures. In lipodystrophia, the disease starts most frequently at about the sixth year or shortly thereafter. It is also true that processes of involution begin in the pineal gland at about the sixth year; much of the gland substance disappears, and cysts, glia plaques, and the like develop. One might assume that, if a certain part is especially affected, it in turn would so influence a certain part of the center as to cause fat atrophy in only the upper part of the body. It has also seemed to others that the distribution of the fat atrophy must be explained on a neurologic basis. Wolff and Ehrenclou[9] report a case of facial hemiatrophy and hemiatrophy of the tongue together with lipodystrophia, a perversion of sensation and a peculiar affective state. They conclude that the facial hemiatrophy is merely the outstanding feature of a syndrome of general autonomic imbalance resulting from deranged central trophic control. They call attention to such derangements following encephalitis giving rise to obesity, alterations in respiratory rhythm, diabetes insipidus, and so on. These conditions point toward the midbrain and that part of it known to be often profoundly affected by encephalitis; i. e., the thalamic and subthalamic area. The possibility has been suggested[10] of an "encephalitis" infection or toxin involving this area directly or indirectly through the effects of disease on the vasomotor apparatus.

I have gone into this speculation as to etiology more in detail because in the six cases here reported the onset seemed definitely to have followed some trauma to or infection of the nasopharynx, and in the reported cases there are thirteen in which the onset dated from such conditions as measles, pertussis, influenza, pneumonia, tonsillitis, tonsillectomy, and otitis media. In my cases, two followed tonsillectomy, one tonsillitis, one measles, one measles and pertussis, and one diphtheria, measles, pertussis and tonsillectomy. The close relationship of infections of the upper respiratory tract to encephalitis with its favorite localization in the midbrain suggests strongly the possibility, at least that there may be some etiologic connection in this disease.

The question of etiology is handicapped by the fact that these patients do not die of this disease and to date records of only two autopsies are at hand: Husler's[11] case and one reported by Weber and Gunewardene.[12] In neither of these was there any definite clue to the cause of the disease. Biopsy reports by several authors show a complete absence of subcutaneous fat, with only a few fat globules in the sebaceous glands.

SUMMARY

Six cases of lipodystrophy in children are reported. In all, the loss of subcutaneous fat was first noticed soon after a definite and severe infection of the upper respiratory tract or tonsillectomy.

None showed any laboratory or clinical evidence of disturbance of the endocrine glands.

Emphasis is laid on the possibility that toxic or infectious derangement of central trophic centers in the thalamic and subthalamic areas of the midbrain may be the main etiologic factor.

Clinical Notes, Suggestions and New Instruments

SERUM TREATMENT OF TULAREMIA *

Lee Foshay, M.D., Cincinnati

Ten cases of acute tularemia have been treated with a specific antiserum prepared from a goat inoculated with formaldehyde-killed suspensions of Pasteurella tularensis. The therapeutic responses have been sufficiently definitive to justify a preliminary report.

Usually about 10 cc. of serum has been given intravenously to each patient on both the first and the second day in the hospital. No serum reactions have occurred. In nine cases there has occurred an abrupt cessation of fever, malaise, chills, sweats, arthralgias and myalgias forty-eight hours after the second injection, and also a rapid reduction in the volume of the involved lymph glands to an average of one half of their former diameters. Not a single lymph gland has suppurated. The skin rash, when present, has likewise either disappeared or faded extensively within the first three days. One patient, received in a dying condition, was not benefited.

A detailed report of these and possibly of other cases will be rendered after the present rabbit season has passed. For the present, the antiserum, if used early, gives promise of being a potent, reliable and satisfactory therapeutic measure for tularemia.

PRIMARY ABSCESS OF THE EPIGLOTTIS

J. Allan Weiss, M.D., Chicago

The cartilages of the larynx are subject to a variety of diseases and traumatic influences of endogenous and exogenous origin. Infection may extend to the larynx from adjacent inflammatory processes in the lingual or faucial tonsils, the pharynx, the nasal sinuses or the deep tissues of the neck through the blood vessels, the lymphatics or by direct continuity. Ballin[1] and S. Cohen[2] have commented on the rarity of abscess of the larynx, considering the universal occurrence of infections of the upper respiratory tract which frequently terminate in localized abscesses in the tonsillar, peritonsillar or retropharyngeal regions. Suppuration of the larynx also occurs as a secondary infection superimposed on syphilitic, malignant or tuberculous infiltration; following necrosis of cartilage due to excessive radium or roentgen therapy or to pressure of tracheotomy or intubation tubes; after perichondritis complicating typhoid, influenza, pneumonia, diphtheria or the exanthems; as a metastatic lesion in ulcerative endocarditis or pyemia, or as a sequel to stab-wounds or fractures.

Primary abscess of the epiglottis, however, has been infrequently reported. Semon[3] found the epiglottis involved in ten of a series of fourteen cases of acute suppuration of the larynx observed in a period of twenty years. In two of these cases the infection was limited to that cartilage but in only one was the process primary. In a group of twenty cases of epiglottic inflammation reported in the English literature, eight were deemed to originate there.[4] Abscess of the epiglottis may be considered primary when it occurs in the absence of preceding underlying disease of that structure or of demonstrable infection elsewhere.

The following case is illustrative:

REPORT OF CASE

L. R., a man, aged 42, an executive, seen, September 16, complained of malaise and mild soreness on swallowing. His temperature was 99.4 F. On examination no acute disease could be found in the ears or nose. The tonsils were small and not injected. There were no palpable cervical glands. The pharynx showed a low-grade chronic injection consistent with the patient's habit of excessive smoking. With a laryngeal mirror no acute inflammation was evident in the lingual tonsil, arytenoids or vocal cords. The epiglottis, however, presented a reddened, hyperemic and glistening lingual surface.

The usual treatment for acute laryngitis was instituted. The following day there was seen some increase in the swelling and the patient complained of a feeling of a "lump in the throat" and frequent hawking, productive of small amounts of mucus. The temperature was 100.2 F. The epiglottis was swabbed with equal parts of 1 : 1,000 epinephrine chloride and 10 per cent zinc sulphocarbolate solutions. September 18, two days after the onset of symptoms, after an uncomfortable night due to marked soreness and fulness of the throat, increased dysphagia and coughing, the patient was removed to the hospital.

At this time there was an increased frequency of respiration with slight difficulty on inspiration, which was noisy but not stridorous. There was no cyanosis or retraction of the infrasternal or supraclavicular spaces. The voice was guttural but not hoarse. The general condition was excellent and there was no air-hunger, restlessness or exhaustion. The temperature was 100.6 F., and the leukocyte count was 18,800, with 72 per cent polymorphonuclear leukocytes. General examination was essentially negative. A laryngoscopic examination revealed the epiglottis as a spherical mass about three times normal size, overhanging and partially blocking the vestibule of the larynx. The swelling obscured the outline of the cartilage but was limited to the anterior surface, which was smooth, glistening, boggy to the touch with a probe, and bright red except for two pea-sized white areas of localized necrosis. The larynx was hidden from view except for part of the arytenoid cartilages, which were not swollen. When the epiglottis was drawn forward with a curved probe, a portion of the vocal cords could be seen to be normal in appearance and mobility.

Though the immediate indication was not urgent, it was considered advisable to relieve the mechanical obstruction by incisions to promote drainage. The epiglottis was anesthetized by topical application of a 10 per cent cocaine-epinephrine solution. Under indirect laryngoscopy, with the use of a curved guarded-blade larynx knife of the plunger type, punctures were made through the two softened areas, allowing escape of seropurulent fluid. The dyspnea improved rapidly and was gone by the next morning, when the swelling had decreased enough to permit a view of the posterior third of the vocal cords. The mucosa now was dry, glazed, lax and dull red, with pus exuding from the puncture openings.

Expectoration of droplets of pus continued for several days. Drainage was aided by probing the incisions daily, after removing small plugs of necrotic tissue. Soreness, dysphagia and muffled speech gradually disappeared. September 22, four days after operation, the epiglottis was normal in size and contour, but still slightly hyperemic. The temperature and white blood count were normal. Culture of pus from the knife blade showed a growth of Staphylococcus albus. The Wassermann reaction of the blood was negative.

COMMENT

The moderate elevation of temperature, the limitation of inflammation to the epiglottis, and the absence of local extension or systemic manifestations were evidence of the relatively mild nature of the infection in this case. This is compatible with the isolation of Staphylococcus albus as the causative organism.

Mild cases may respond to medical measures. In this instance, however, the swelling was sufficient to require multiple incisions to relieve mechanical embarrassment to respiration and to avoid a greater degree of dyspnea, which would follow extension to the arytenoid cartilages, aryepiglottic folds or false cords, directly encroaching on the glottis.

ANATOMIC DISCUSSION

Restriction of infiltration to the anterior aspect of the epiglottis is the usual finding in most cases. This is due to the looseness of the areolar connective tissue of the submucosa in this location. Hajek [5] has shown experimentally that fluid may extend to the glosso-epiglottic fossa at the base of the tongue but is confined to the lingual surface of the epiglottis by the firm attachment of the mucosa, anteriorly, to the free margin of the cartilage and, laterally, to the pharyngo-epiglottic folds. However, Logan-Turner [6] indicated that these connections constitute merely an anatomic barrier to edema or moderate infections. Severe infections may extend to other parts of the larynx or to the deep cervical tissues by continuity of the mucosa.

ETIOLOGY

The general factors predisposing to acute epiglottitis are similar to those of catarrhal laryngitis, including chilling by exposure to wet and cold, excessive use of alcohol or tobacco, debilitating influences as mental or physical strain, malnutrition, autointoxication and chronic organic diseases. Inhalation of irritating vapors or aspiration of very hot or corrosive liquids may result in devitalization of the protective mucosa. Also, the epiglottis may be directly traumatized by foreign bodies, bones or sharp food particles, which may cause an abrasion providing an atrium for the resident bacterial flora of the throat. Such an accident may be so slight as to be unnoticed by the patient or dismissed as insignificant at the time of occurrence. This is the presumable cause in the case reported.

However, direct trauma is probably not the major factor in primary involvement of the epiglottis. It is difficult to correlate the low incidence of lesions of this structure with its seeming vulnerability to injury due to its prominent position at the entrance of the larynx and its protective function as trap-door to the tracheopulmonary system.

The bacteriology is varied, though some type of streptococcus is the most frequent offender. In thirteen cases of epiglottic suppuration in which cultures were reported, Streptococcus hemolyticus was found in pure culture in six cases and in mixed infection in four cases. Other organisms found included Bacillus influenzae, B. coli, B. pyocyaneous, Micrococcus catarrhalis, Staphylococcus aureus and the pneumococcus. In twenty-eight cases of diffuse laryngotracheobronchitis, Bradford and Leahy [7] found Streptococcus viridans predominating.

SYMPTOMS

In severe cases, symptoms of hoarseness, dysphagia, wheezing and external tenderness occur. Increasing dyspnea with cyanosis, restlessness and retraction of the soft tissues of the chest on inspiration indicate extension to the interior of the larynx.

In fulminating infections, usually of streptococcic origin, high fever, chills and prostration supervene as evidence of pneumonia, or of pyemia, often with localizing signs of involvement of the heart, pleura, pericardium, peritoneum or joints. Direct extension to the deep tissues of the neck or to the mediastinum may occur.

TREATMENT

In addition to general "cold" management, in earlier stages the use of external and internal cold applications and also sprays of epinephrine, ephedrine or cocaine to the epiglottis are of value to shrink the swelling. Multiple incisions are often necessary to reduce engorgement or provide drainage.

In threatened asphyxia, prompt establishment of an airway is imperative. Although tracheotomy carries the hazard of subsequent pneumonia, it affords an easier and more positive method of maintaining breathing without the injury to inflamed tissues caused by intubation. Supportive measures to sustain the patient and specific treatment are necessary when complications arise.

SUMMARY

Primary abscess of the epiglottis is rare despite the universal occurrence of infections of the upper respiratory tract. A case is reported which required multiple incisions and drainage to relieve obstruction to breathing.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application.

W. A. Puckner, Secretary.

SODIUM IODOBISMUTHITE.—Sodium bismuth iodide.—A compound formed by the interaction of bismuth chloride and sodium iodide in ethyl acetate solution, consisting essentially of hydrated sodium iodobismuthite (sodium bismuth iodide) Na_2BiI_5, with inorganic salts. It contains approximately 21 per cent bismuth (Bi), 62 per cent iodide (I^-) and 11 per cent water of hydration.

Actions and Uses.—It is claimed for this new bismuth preparation, sodium iodobismuthite, that it has the quality of appearing in the spinal fluid and of penetrating the brain tissue.

Dosage.—See Iodobismitol.

Sodium iodobismuthite occurs as a red crystalline compound, odorless, or having only a faint acetic or ethyl acetate odor, permanent in dry air and possessing an astringent taste. It yields a clear solution with one part water; on moderate dilution of the solution, sodium iodobismuthite hydrolyzes to form a black precipitate of bismuth iodide in a finely divided state, while on further addition of water the black precipitate changes to red bismuth oxyiodide. Hydrolysis may be retarded by the addition of acids or alkali iodides. The aqueous solution is neutral or faintly acid to litmus. Sodium iodobismuthite dissolves readily and without decomposition in ethylene-glycol, propylene glycol, glycerin, anhydrous alcohol and ethyl acetate; it is insoluble in absolute ether, chloroform, carbon disulphide, petroleum ether, fixed oils and liquid petrolatum. On heating the product in an oven at 80 to 110 C., it loses water of hydration, with slight decomposition, leaving a maroon colored residue that becomes brown or black on aging, and that changes to red on exposure to moisture.

Add 3 cc. of hydrochloric acid and 25 cc. of water to about 0.5 Gm. of sodium iodobismuthite, add an excess of stronger ammonia water, filter and wash the filter with water. Ignite the filter in a quartz crucible; the residue is yellow. A few drops of the filtrate imparts an intense yellow color to a nonluminous flame. Add 3 cc. of ferric chloride solution to a 10 cc. portion of the filtrate acidified with hydrochloric acid, shake with 3 cc. of chloroform; a violet coloration is imparted to the chloroform. Add 5 cc. of chloroform to about 0.2 Gm. of sodium iodobismuthite and shake the mixture; the chloroform remains clear and colorless (*free iodine* and *distinction from quinine bismuth iodide*). Percolate 0.1 Gm. of sodium iodobismuthite with 10 cc. of absolute ether; no residue remains after the evaporation of the solvent. Add 2 cc. of nitric acid to 1.5 Gm. of sodium iodobismuthite in a quartz dish, evaporate on a steam bath and ignite at red heat; dissolve in 5 cc. of hydrochloric acid; the solution meets the requirements of the Bettendorff test, U. S. P. X (*arsenic*). Add just sufficient nitric acid to blacken 3 Gm. of sodium iodobismuthite contained in a 150 cc. beaker, add 100 cc. of water and boil; filter and evaporate the filtrate to 30 cc., filter again and divide the latter filtrate into portions of 5 cc. each. Mix one portion with an equal volume of dilute sulphuric acid: the liquid does not become cloudy (*lead*); precipitate another portion with a slight excess of ammonia water: the supernatant liquid does not exhibit a bluish tint (*copper*); another portion is not immediately affected by barium nitrate solution (*sulphate*). To another portion, add diluted hydrochloric acid; no precipitate is formed which is insoluble in a slight excess of hydrochloric acid, but soluble in ammonia water (*silver*).

Transfer about 0.4 Gm. of sodium iodobismuthite, accurately weighed, to a wide mouth weighing bottle and heat to constant weight in an oven at 110 C.; the loss in weight is not less than 10.5 per cent nor more than 12.5 per cent.

Transfer about 0.2 Gm. of sodium iodobismuthite, accurately weighed, to a beaker, dissolve in 3 cc. of hydrochloric acid and 125 cc. of water, saturate the solution with hydrogen sulphide to precipitate completely the bismuth as bismuth sulphide, filter in a gooch crucible, wash with water, alcohol, chloroform and ether in this order, dry for one hour at 100 C., cool in a desiccator and weigh; repeat the washing with chloroform and ether and the drying at 100 C. until constant weight is attained; the bismuth sulphide weight is equivalent to not more than 21.8 per cent, nor less than 20.3 per cent bismuth.

Transfer about 0.2 Gm. of sodium iodobismuthite, accurately weighed, to a 250 cc. beaker, add 10 cc. of a solution of acid silver nitrate (prepared by dissolving 1 Gm. of silver nitrate in 20 cc. of water and adding 5 cc. of nitric acid) and then 100 cc. of water, allow to stand two hours, filter, using a filter paper, wash well with water. Without allowing the precipitate to dry, puncture the filter and wash the precipitate into a 250 cc. glass-stoppered erlenmeyer flask, using 100 cc. of stronger ammonia water, agitate the solution, then allow the flask and contents to stand two hours, collect the precipitate on a prepared gooch crucible and wash it with diluted ammonia water, then with water; dry to constant weight at 100 C. The weight of silver iodide is equivalent to not less than 60 per cent nor more than 63 per cent iodide. Add 10 cc. of potassium iodide solution to the filtrate and heat on the steam bath until most of the ammonia has been removed, filter the solution and collect the precipitate on a prepared gooch crucible, wash with water, dry to constant weight at 100 C.; the weight of silver iodide is equivalent to not more than 0.7 per cent chloride.

IODOBISMITOL.—A solution of sodium iodobismuthite (sodium bismuth iodide) in ethylene glycol containing 0.1 per cent acetic acid. Each cubic centimeter contains sodium iodobismuthite equivalent to 0.012 to 0.0138 Gm. bismuth (0.0577 Gm. to 0.0664 Gm. sodium bismuth iodide) and 0.109 Gm. to 0.129 Gm. sodium iodide. The total iodide is equivalent to 0.159 Gm. to 0.171 Gm. sodium iodide per cubic centimeter.

Actions and Uses.—Iodobismitol seems to be well absorbed and to be excreted fairly rapidly. In laboratory animals the bismuth enters the brain in from 90 to 100 per cent of the cases, and in human beings treated with the drug it has been shown in the spinal fluid in over 90 per cent of the cases. The claim is made for it that it will penetrate the brain in a great majority of persons treated.

Dosage.—Intramuscular injections of 2 cc. repeated every three days. Two full days should elapse between injections. From eight to twelve injections comprise a course of treatment. A rest period of from two to four weeks should elapse between courses. At each injection the patient would thus receive from 0.024 to 0.0276 Gm. metallic bismuth (0.1154 to 0.1328 Gm. sodium bismuth iodide, and from 0.218 to 0.258 Gm. sodium iodide).

Manufactured by E R. Squibb & Sons, New York, by license of Stanford University. U. S. patent applied for.

The specific gravity of iodobismitol at 25 C. ranges from 1.236 to 1.238. The pH of iodobismitol taken with a quinhydrone electrode ranges from 4.5 to 5.0.

Transfer about 3 cc. of iodobismitol, accurately weighed, to an erlenmeyer flask, add 3 cc. of hydrochloric acid and 125 cc. of water; determine the bismuth according to method outlined under sodium bismuth iodide. Each cubic centimeter contains the equivalent of not less than 0.012 nor more than 0.0138 Gm. Bi.

Add 10 cc. of a nitric acid silver nitrate solution (prepared by dissolving 1 Gm. of silver nitrate in 20 cc. of water and adding 5 cc. of nitric acid) to about 3 cc. of iodobismitol, accurately weighed, and then add 100 cc. of water, allow to stand two hours, filter into a prepared gooch crucible and wash with very dilute nitric acid (5 cc. diluted nitric acid to make 100 cc.), dry to constant weight at 100 C. The weight of silver iodide is equivalent to not less than 0.135 nor more than 0.145 Gm. iodide per cubic centimeter.

The sodium iodobismuthite in iodobismitol conforms to the N. N. R. standards for this substance.

PRELIMINARY REPORTS OF THE COUNCIL

The Council has authorized publication of the following report.

W. A. Puckner, Secretary.

GONOCOCCUS BOUILLON FILTRATE (GONOCOCCUS TOXIN)

In this issue of The Journal, page 532, there appears the preliminary report of Dr. B. C. Corbus, "Intradermal Immunization in Gonorrhea," concerning the experimental and clinical work with a gonococcus bouillon filtrate developed by Clark and Ferry of the Research Department of Parke, Davis & Co. In 1930, Parke, Davis & Co. informed the Council in a preliminary way in regard to the investigation of the product then under way. Later, at the request of the Council the product, together with a copy of the paper by Clark, Ferry and Steele, "Studies of the Properties of a Bouillon Filtrate of the Gonococcus," was presented by the firm for consideration by the Council. In presenting the product, Parke, Davis & Co. stated that the firm regarded it as being entirely on an experimental basis. Dr. Corbus submitted the manuscript of his present paper, a reprint of his paper in collaboration with O'Conor, "Intradermal Injections of Gonococcal Bouillon Filtrate. An Experimental Report" (*J. Urology*, September, 1930), and the manuscript of two other papers. He also submitted letters from a number of physicians who had used the product.

The submitted information and papers were submitted to a consultant of the Council, who reported that the studies of Clark and Ferry showed that their method had produced a soluble and filtrable toxic substance from the gonococcus. Concerning the papers of Corbus and of Corbus and O'Conor, the consultant stated that although these give in great detail the method and indications for treatment by this gonococcus bouillon filtrate under various clinical conditions, there is lack of suitable controls and no data are adduced to support the claim that the product is a satisfactory treatment. The consultant found a number of the letters of physicians submitted by Dr. Corbus to be favorable to the product, others neutral or negative; but taken as a whole these letters did not modify his conclusion that the evidence is inadequate to warrant general use of the product. The Council's referee concurred in the opinions of the consultant, agreeing wholly with the position of Parke, Davis & Co. in not making the preparation available for general use.

While the product itself is, according to the information submitted, of sufficiently controlled composition, the evidence for its clinical value is insufficient, certainly not convincing enough to take it out of the experimental class or to warrant its recommendation for general use. The Council therefore postponed consideration of Gonococcus Bouillon Filtrate (Gonococcus Toxin) to await the development of confirmatory evidence of its clinical value.

Committee on Foods

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary.

HYGEIA PURE STRAINED PEAS

Contains Vitamin D

Added Irradiated Ergosterol

Manufacturer.—The Snider Packing Corporation, Rochester, N. Y.

Distributor.—Hygeia Nursing Bottle Company, Buffalo, N. Y.

Description.—Strained peas retaining in large measure the mineral and vitamin content of the raw peas used; with added vitamin D (irradiated ergosterol), 60 D units per fluidounce; packed in jars. The D units are those defined by the Council on Pharmacy and Chemistry of the A. M. A. (New and Nonofficial Remedies, 1931, p. 414). One fluidounce is equivalent in vitamin D to the D content of one teaspoonful of cod liver oil. No sugar or seasoning is added.

Manufacture.—The Alaska late variety peas used are grown under contract, and harvested at an early stage of maturity; are removed from the vines by machine, passed through a blowing mill to remove splits and foreign material, washed, blanched for eight to ten minutes in water at 99 C., passed over a sorting table for removal of foreign material, filled into No. 10 enamel lined cans, and a small amount of hot water (90 C.) is added. The cans are sealed and processed for sixty-five minutes at 116 C. No salt or sugar is added.

In preparation for pureeing, the cans of peas are heated in hot water at 82 C., opened and inspected, and the contents are pumped to a paddle type pureeing machine of monel metal with a bronze rotor. Steam is injected into the enclosed pureeing machine to displace the air. The pureed peas are pumped into closed tin lined steam jacketed kettles at as low a point as possible. Steam is injected into the covered kettles to replace the air. The pureed peas are thoroughly mixed with 10 per cent of water to bring about the desired consistency and a definite quantity of irradiated ergosterol dissolved in corn oil is added. The irradiated ergosterol added is sufficient to effect a vitamin D potency equivalent to one teaspoonful of standard cod liver oil per fluidounce of finished product. The mixture is heated, pumped to an automatic filling machine, and filled into washed and preheated jars. The jars are capped under 10 to 14 inches mercury pressure in "vacuum" closing machines, processed for seventy minutes at 115 C., cooled under pressure, and stored for later examination.

Chemical Composition (submitted by manufacturer).—

Specific gravity 20 C./20 C.	1.05
	per cent
Moisture	85.0
Total solids	15.0
Ash	0.5
Fat (ether extract)	0.4
Protein (N × 6.25)	4.6
Starch (acid hydrolysis method)	4.8
Crude fiber	0.5
Carbohydrates other than crude fiber (by difference)	9.0
Calcium (Ca)	0.02
Iron (Fe)	0.001
Phosphorus (P)	0.02

Calories.—0.6 per gram; 17 per ounce.

Vitamins.—The vitamin content of the raw peas is retained in maximum degree in the manufacturing process by the use of equipment and procedure which excludes admixture with air; the vegetable material is exposed to steam atmosphere only. The jarred sieved vegetable is "vacuum treated" before the final processing to remove any incorporated air.

Vitamin D is incorporated in the pureed material to yield a vitamin potency of 60 D units per fluidounce of final product. The D units are those defined by the Council on Pharmacy and Chemistry of the A. M. A. (New and Nonofficial Remedies, 1931, p. 414). The vitamin D is added under license grant from the Wisconsin Alumni Research Foundation under the Steenbock patent.

Claims of Manufacturer.—The sieved peas are recommended for infants, children and convalescents and in special diets. The peas are scientifically prepared to retain to a maximum degree, or so far as is possible by present commercial sieving and canning methods, the natural mineral and vitamin values of peas.

FRANCK TABLETS

A Pure Roasted Chicory Product

Manufacturer.—Heinr. Franck Sons, Inc., Flushing, N. Y.

Description.—Roasted chicory root; ground and pressed into tablets.

Manufacture.—Chicory roots are grown from imported seed usually alongside sugar beets. The operations of harvesting are essentially the same as for sugar beets; lifting, pulling and topping. The roots are washed by machine, sliced, dried in drying kilns, cooled, cleaned of sand and dirt by special machines and roasted for from two to two and one-half hours, after which they are cleaned of ashes and adhering foreign material and finally ground for powdered chicory or crushed for granulated chicory. The chicory in the form of tablets is packed in cartons; the granulated or powdered form is sold in bulk.

Chemical Composition (submitted by manufacturer).—

	per cent
Moisture	3.5
Ash	4.7
Water soluble ash	2.9
Acid insoluble ash	0.4
Fat (petroleum ether extract)	3.6
Protein (N × 6.25)	7.3
Crude fiber	7.9
Reducing sugars as invert	8.6
Sucrose (copper reduction method)	0.4
Total carbohydrates other than crude fiber (by difference)	73.0
Water extract	69.0

Calories.—2.5 per gram; 71 per ounce.

Claims of Manufacturer.—The roasted chicory tablets are suitable for addition to coffee beverage.

PAUL'S SANDWICH BREAD

Manufacturer.—Paul's Baking Corporation, Chicago.

Description.—A white bread made by the sponge dough method.

Manufacture.—The sponge dough ingredients, short patent flour of southwest and northwest wheats, water, yeast and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate, are mixed in a high speed mixer. The sponge dough is fermented for from four to five hours, after which are added flour, water, salt, sucrose, lard and sweetened condensed skim milk to make the completed dough, which is cut into pieces of desired weight. The pieces are fermented for a short time, molded into loaf form, panned, fermented, baked for from thirty to thirty-five minutes, cooled, and wrapped in wax-paper.

The factory, equipment and storage rooms are kept in strictly sanitary condition.

Chemical Composition (submitted by manufacturer).—

	per cent
Moisture (entire loaf)	35.3
Ash	1.8
Fat (ether extract)	2.8
Protein (N × 6.25)	10.0
Crude fiber	0.3
Carbohydrates other than crude fiber (by difference)	49.8

Calories.—2.6 per gram; 74 per ounce.

Claims of Manufacturer.—A bread of good quality.

FOOD AND HEALTH—A STUDY OF CONSUMERS' HABITS

Knowledge about nutrition seems to be in a state of continual flux. Fifteen years ago Mendel[1] of Yale University, addressing the second Pan American Scientific Congress at Washington, remarked that man no longer depends on his instincts alone for guidance in the affairs of life; otherwise progress would indeed be slow. He pointed out that the problem of food supply is not one which can be dismissed by the social philosopher or solved by the calculations of the economist. It is highly complex with its involvement of factors and interests in agriculture, commerce, industry and nutrition. Here, as in other domains, there is opportunity for an interplay of science and the arts, of experience and investigation. To attempt to foretell the future seems more like an act of ill considered rashness than a keen intellectual venture. We are beginning to learn what real food values mean. There is as yet no ideal ration.

There can be no doubt that changes in the food habits and dietary standards of persons are going on in many parts of the world. It is not always easy to analyze the underlying causes for such dietary changes; they are not always merely physiologic or dominantly economic in origin, as one might expect. Rubner once remarked that sometimes revolutions occur in the field of popular nutrition. The introduction of the potato in many extensive regions is cited as an illustration.

Today our prescribed diets are tending to become more and more complex. In an engaging volume on nutrition and physical fitness, Bogert[2] has asserted that, while a varied diet has many advantages, it is not essential to securing good nutrition. In the simpler civilizations of the past and at present in many parts of the world where, for one reason or another, the food supply is limited, peoples have been and still are being brought to a high degree of physical development and maintained in great sturdiness on diets that consist of only a few foods. Bogert adds that we have in our present-day highly industralized civilization a situation in which, with a wider range of foods to choose from than any people has ever had before, the nutritional condition and physical vigor of our nation has unquestionably deteriorated.

Without accepting this challenge in regard to the "state of the nation," so far as the bodily welfare of the people is concerned, it may nevertheless be admitted that current customs with respect to foods are not devoid of surprising vagaries. A recent writer[3] ventures to believe that American food habits have not been developed as a result of necessity but are matters of choice or fancy. Changes in the proportions of different foodstuffs grown or manufactured have been based largely on what people could be induced to buy rather than to supply a population ready to purchase whatever foodstuffs were available. This situation, Sherman concludes, has led to a great deal of advertising and propaganda to induce consumers to change their food habits. Among the inducements offered have been novelty, attractiveness, convenience and, most successful of all, health appeal.

A few illustrations regarding our changing choices of food are elucidating. Sugar, once consumed in quantities less than ten pounds per annum for each person, is now used to ten times this extent—more than a hundred pounds in the course of the year. Greater availability and low costs have transformed what was merely a condiment into a food that supplies one seventh or more of the nation's calories. Within ten years the haulage of spinach on the railroads has increased, despite the protests of American children importuned to eat it, from 2,500 carloads to 10,000 carloads a year; lettuce shipments have been quadrupled within the decade. The citrus fruit industry has been rescued from the grave dangers of overproduction. New dietary customs have been initiated.

Wisdom is by no means always the guide in these changes. Sherman[3] has pointed out the almost universal habit of selecting foods by the eye and the difficulty encountered in attempts to substitute any more scientific test in the place of the visual. In the development of commercial grades and standards for fruits and vegetables we are constantly confronted with the fact that commercial values are largely dependent on appearance. If our first, second and third grades for any fruit or vegetable are to represent differences in commercial value we find ourselves often compelled to give major weight to factors that have no dietetic significance. Recent emphasis on the value of certain "greens" as "protective foods" may be responsible for certain current absurdities in practice. As pointed out by Sherman,

> Certainly there is little to be said in defense of our recently developed habit of shipping tens of thousands of carloads of carrots, beets, turnips, radishes, and even parsnips for

> thousands of miles, paying freight upon countless tons of tops which no one uses and which, if they arrive wilted, or decayed, are a positive detriment to the product. With the exception of a very few beet leaves, these vegetable tops all go into the garbage can, as do the green stems which surround the head of the cauliflower, and the outer leaves of all cabbage and lettuce. Here, it seems to me, is an enormous economic waste and one which is growing annually.
>
> All of these southern and Pacific Coast vegetables shipped fresh under refrigeration with tops or green foliage attached bear a freight rate which, in many cases, represents nearly fifty per cent of the delivered value of the product. It is safe to say that in the case of many of these products about thirty per cent of the bulk, and perhaps fifteen to twenty-five per cent of the weight, consists of tops and leaves which finally disappear as trimmings. The heavy transportation and icing charges which have been paid on this useless foliage must be recovered in the price of that part of the goods actually consumed.
>
> If it should prove that we are now nearer the beginning than the end of a period of economic readjustment, and if before it is ended the average American family will be willing to give more careful thought to the cost and character of its food than it has been necessary to do in recent years, it may be well for us to consider the possibility of modifying the consumer's point of view so that she will not demand that freight be paid upon so much garbage which she never uses but which adds materially to the cost of what she does use.

American food habits should become rationalized with respect alike to health and to economy at a time when distress is threatening thousands of persons.

EXPERIMENTAL NEURO-ALLERGY

In 1930 Dr. D. A. Shamburov[1] of the Neuropsychiatric Institute, Moscow, claimed that stock vaccines may be injected with safety into the cerebrospinal fluid and that so injected they exert a favorable influence on certain chronic infections of the central nervous system. More recently two important studies have been made by American investigators[2] of the immunophysiology of subarachnoid and nervous tissues having a direct bearing on the feasibility of Shamburov's proposed local vaccination. In his preliminary experimental work on rabbits the Russian investigator showed that by routine subcutaneous or intraperitoneal injections of vaccines the specific antibody titer of the cerebrospinal fluid cannot be raised higher than from 0.125 to 0.25 per cent of the corresponding titer of the blood stream. By injecting the same vaccines by suboccipital puncture into the subdural space, however, he found that the antibody content of the cerebrospinal fluid could be increased to as much as 20 per cent of that of the circulating blood and that it remained at this unusual high titer for at least two months. Shamburov assumed that this high local antibody titer must logically exert a favorable influence on homologous chronic infections of the central nervous tissue. A criticism of this logic is implied in the more recent studies of the antibody content of nervous tissues by Dr. Jules Freund[2] of the Phipps Institute, Philadelphia. Freund found that in both active and passive immunization the specific antibody titer of the central nervous tissues of rabbits is at least three times greater than that of the surrounding cerebrospinal fluid. From this he was forced to conclude that "it is very unlikely that . . . antibodies reach the brain tissues by way of the cerebrospinal fluid," the cerebrospinal fluid apparently being a mere mechanical drainage fluid from the interstitial tissue spaces. If this conclusion is correct the cerebrospinal fluid can have little or no local immunologic action except on the meningeal surfaces with which it is in immediate contact. There is therefore reasonable doubt that the Shamburov technic for local vaccination can influence local infections of the central nervous tissues, except indirectly by absorption of the locally synthesized or locally mobilized antibodies into the systemic blood stream.

The most serious objection to the proposed subarachnoid vaccination, however, is implied in the currently published researches of Davidoff and Kopeloff[2] of the Psychiatric Institute, New York. These investigators developed a new technic for the study of neuro-allergies. They trephined dogs over the left motor area and inserted into the underlying cerebral tissues a small cube of normal horse serum stiffened with 6 per cent agar, followed by a routine sensitizing dose of horse serum intravenously. The slight transient hemiplegia resulting from the purposeful [sic] injury to the cerebral cortex disappeared within a few days. At the end of the usual sensitization period the dogs were tested by an intravenous injection with a sublethal dose of horse serum. In four of the five dogs thus far studied by this dual technic the classic picture of anaphylaxis was complicated by a "definite right-sided hemiplegia within a few minutes after the intravenous injection." American clinicians will not be tempted to use the Shamburov local subarachnoid vaccines till more extensive experimental studies have been made of this potentially dangerous local neuro-allergy.

PHYSICAL TRAINING AND METABOLISM

In his volume on the physiology of muscular exercise, Bainbridge[1] remarked more than a decade ago that the real value of exercise probably lies mainly in its effects on the metabolism of the tissues themselves. Some investigators have looked to changes in the heart and in the circulatory and respiratory mechanisms as the foremost factors involved in that adjustment described as physical training. The trained athlete is supposed to work more "efficiently" than his untrained companion; but as efforts to interpret the advantage in terms of increased efficiency of breathing or circulation alone have not been convincing in every instance, one must look elsewhere for a tenable explanation. The muscle cells at once suggest themselves as the center

of interest. Is their characteristic exchange of energy altered? If so, this should exhibit itself in an altered basal metabolism. Recognizing that metabolism is a cellular process, that each living cell uses its share of the total oxygen absorbed by the individual, Schneider[2] has pointed out that our real problem is to determine whether or not the cellular processes of the body are accelerated, retarded or unaltered by training. If the cells are stimulated to increased activity, they will use more oxygen; but if the life process becomes more efficient, they will use less oxygen. Training may so affect the cells that they will use, even in rest, more oxygen or less oxygen than formerly; or it may not alter their usage of oxygen. There is a widespread opinion, Schneider continues, that the body is physically and mentally more efficient if regular physical exercise is taken. While we cannot at present prove that cellular metabolism becomes more efficient as a result of training, if we assume that it does an explanation is at hand for the fall in the basal metabolism seen in some athletes and nonathletes during a period of training.

The facts as determined by Schneider and his co-workers at Wesleyan University in Middletown, Conn., indicate that the basal metabolic rate of all men does not respond in the same manner to a period of physical training. Of seven nonathletes who were under observation during periods of daily moderate physical exercise, three showed an appreciable fall, two a rise, and two no change in the metabolic rate. Among ten athletes, eight showed a drop in the basal metabolic rate during training, one an increase, and another no change in the rate. The literature on this subject reveals that some workers in this field have reported that physical training causes a rise while others have reported that it causes a fall in basal metabolism.

An ingenious interpretation of these seeming contradictions has been offered by Schneider. If, as already remarked, the life processes in the muscle cells become more efficient through use, they may require less oxygen. Their basal metabolism will fall. On the other hand, if a period of physical training should at the same time result in an increase in the mass of active tissue in the body, we must assume that the added protoplasm requires its share of oxygen and that this increases the total oxygen requirement of the body.

Somewhat antagonistic influences may thus present themselves as the result of training. In the words of Schneider: If during a period of training the gain in cellular efficiency overbalances the gain in the mass of body protoplasm, a fall in the basal metabolic rate will result. If, on the other hand, there occurs a considerable increase in the size of muscles, due to a formation of active protoplasm, this may overshadow the gain in cellular efficiency and result in an increase in the basal metabolism. Lastly, if the increase in efficiency should just be counterbalanced by the new production of protoplasm, the basal metabolic rate of the individual would remain unchanged during a period of physical training. From such standpoints the apparent inconsistencies in our current information become at least less disconcerting to a critical reviewer.

Current Comment

PHYSICIANS' INCOME TAXES

Physicians are advised to file their federal income tax returns without further delay. They must be filed not later than March 15. The congressional committee that is drafting new income tax legislation has not submitted a report. It has been announced, however, that such changes as may be agreed on will not affect taxes payable under the present law and computed on the basis of income received in 1931. The possibility of having to file supplemental returns if regular returns are filed now seems therefore to be negligible. Elsewhere in this issue of The Journal[1] is a statement for the guidance of physicians in filing their returns.

OPINIONS ON PRESCRIPTIONS OF ALCOHOL

Hearings before the Senate committee that is concerned with the bill introduced by Senator Bingham to modify the prohibition regulations have brought to light some astounding testimony. Among those who have participated in giving evidence was a former president of the American Medical Association—Dr. Arthur Dean Bevan. It is unfortunate that physicians should testify beyond their scientific opinions regarding the effects of alcoholic liquors on the human body. Dr. Bevan seems to have ventured positive statements on the social effects of alcohol and on the ethical aspects of medical prescribing. In proffering his opinions, Dr. Bevan demonstrated an extraordinary lack of confidence in his professional brethren. He moralized on the terrific temptation confronting the profession through the fact that many physicians have incomes of approximately $2,500 a year and, in the right to prescribe, have seen, in his opinion, an opportunity to make $1,200 extra. Dr. Bevan is apparently familiar with the cost of whisky per case at corner drug stores; he asserted that a considerable number of physicians were providing the signed prescriptions that permitted druggists and bootleggers to sell this liquor by the case. The Journal wishes to protest editorially against this expression of opinion by one of the past presidents of the Association. If Dr. Bevan has actual evidence that any physician is selling his prescriptions *en masse* in order to permit druggists and bootleggers to dispose of whisky in case lots, he, and all of those who possess the information, are equally guilty with those who are violating the law in permitting the violation. If he has not the evidence, he is certainly without warrant in making such a statement to a Senate committee; in any event he is not justified in indicting the entire profession for the misdemeanors of a few. His statement reflects great discredit on a profession whose ideals are certainly as high as those of any other professional group in the country. As a leader of that profession for one year, he should be more familiar than he seems to be with its ethical standards and with the extent to which physicians actually are guided by a proper appreciation of moral values.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Monday from 12 noon to 12:05 p. m. over Station WBBM (770 kilocycles, or 389.4 meters) and other stations of the Columbia Broadcasting System, and on Wednesday and Friday from 2:25 to 2:30 p. m. over Station WBBM, Chicago.

The program for the week is as follows:

February 15.	Trends in Mental Diseases.
February 17.	Prevent Death if Not Disease.
February 19.	Baby's First Bath.

There is also a fifteen minute health talk sponsored by the Association on Saturday morning from 11:15 to 11:30.

The program for the week is as follows:

February 20.	Goiter—Enlargement of the Thyroid Gland.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

Bureau of Sanitary Engineering.—At a special meeting of the board of health of San Francisco, Dec. 14, 1931, a resolution was unanimously adopted requesting the appointment of Charles Gilman Hyde, professor of sanitary engineering of the University of California, as consulting sanitary engineer to the director of public health of San Francisco. This appointment resulted in the formation of a bureau of sanitary engineering. Under a new charter, effective January 8, the title of Dr. Jacob C. Geiger, city health officer, became director of public health.

Two Deaths from Trichinosis.—Two persons died from trichinosis in San Francisco recently, after having eaten undercooked sausage which was received as a gift from a friend in Marin County. The animal from which the sausage was made had been killed, Dec. 17, 1931. Sausage, salami and other products were manufactured on the ranch where the animal was killed. It was thought that at least twelve persons had been exposed, but, according to the bulletin of the state department of health, January 23, the two fatalities were the only cases reported.

Society News.—Dr. Willis C. Campbell, Memphis, Tenn., addressed the San Diego Academy of Medicine, January 19, on "Treatment of Affections of the Lumbosacral Region." He spoke on "Treatment of Ankylosed Joints" before the Los Angeles County Medical Association, January 21.——The San Diego County Medical Society was invited by the commanding officer, U. S. Naval Hospital, to be present at a special program, January 15, when Drs. John V. Barrow gave an address on "Human Amebas"; William C. Boeck, "Colitis," and William H. Daniel, Los Angeles, a proctologic clinic.——Dr. Ellis W. Jones, among others, addressed the Los Angeles Clinical and Pathological Society, January 28, on "Trochanteric Transplantation in Treatment of Fractures of the Neck of the Femur."——Dr. Delbert H. Werden spoke on "Intracranial Venous Anomaly" before the Los Angeles Society for Neurology and Psychiatry, January 27; Drs. George H. Patterson and Arthur R. Timme were also on the program.——Dr. Loyal Davis, Chicago, addressed the Los Angeles Surgical Society, February 12, on "Experimental and Clinical Studies on the Pathways of Transmission of Pain and Its Surgical Relief."——An addition to the department for acute mental disease of Livermore Sanitarium, Livermore, was recently opened; the annex provides eight sound-proof rooms.——At the meeting of the Los Angeles County Medical Association, February 4, the speakers were Drs. Jay J. Crane and George F. Schenck on "Transureteral Resection of Bladder Neck Obstruction"; William Dewey Wightman and Shuler F. Fagan, "Margin of Safety and Technic of Spinal Anesthesia," and Philip J. Murphy, "Diagnosis and Surgical Judgment in Acute Abdominal Pain."——At the meeting of the San Francisco Pathological Society, February 1, the program included addresses by Drs. Margaret Schulze, San Francisco, and Frederick Proescher, Agnew, on "Granulosa Cell Tumor of Ovary" and "Chemistry of Neuroglia Staining," respectively.

COLORADO

Dr. Bloodgood to Conduct Clinics.—Dr. Joseph C. Bloodgood, clinical professor of surgery, Johns Hopkins University School of Medicine, Baltimore, will hold two microscopic-pathologic clinics, February 25-26, under the auspices of the Clinical and Pathological Society of Denver. Dr. Bloodgood will also give a lecture the second day on "What Every Doctor Should Know About the First Sign of Cancer."

Society News.—At the January 19 meeting of the Medical Society of the City and County of Denver, Drs. Duval Prey and Ora S. Fowler spoke on "Procedure That Should Be Routine in the Postoperative Conduct of a Surgical Case" and "Renal Syndrome with Hypocortinism," respectively. Dr. Willis C. Campbell, Memphis, addressed the society, February 2, on arthroplasties.——Samuel J. Lewis, D.D.S., Detroit, addressed the Denver Dental Association meeting jointly with the Denver County Medical Society, February 11, on "Child Growth and Development, with Special Reference to the Development of the Bones of the Teeth and Jaws."

CONNECTICUT

Society News.—At the annual meeting of the Connecticut Public Health Association in Hartford, January 14, the speakers included Drs. Nathan M. Spector, Willimantic, and Harry B. Smith, epidemiologist, state department of health, on "Milk-Borne Typhoid Fever"; Raymond D. Fear, Stamford, and Albert E. Austin, Old Greenwich, "Diphtheria Toxoid," and William F. Wild, Bridgeport, Louis J. Dumont, New Britain, and Benjamin B. Robbins, Bristol, "Smallpox as a Public Health Problem."

Lafayette Mendel Presented with Portrait.—On his sixtieth birthday, February 5, Lafayette B. Mendel, Ph.D., Sterling professor of physiologic chemistry at Yale University School of Medicine, New Haven, was presented with a portrait of himself by John Quincy Adams, Viennese artist. Professor Mendel obtained his B.A. degree from Yale in 1891. He began teaching physiologic chemistry at Yale the following year, and, except for periods of study at Breslau and Freiburg, has been at the school continuously for forty years. He is a member of the governing boards of the school of medicine, Sheffield Scientific School and the Graduate School of Yale University. In 1893, Yale conferred the degree of Ph.D. on him. He was gold medalist of the American Institute of Chemists in 1927. Professor Mendel is well known for his analysis of the value of food constituents as shown by their influence on growth.

DISTRICT OF COLUMBIA

District Bills in Congress.—S. 1569 has passed the Senate, authorizing the Commission on Licensure to Practice the Healing Art to license Della D. Ledendecker to practice chiropractic in the District of Columbia.

FLORIDA

No Deaths from Diphtheria.—According to the annual report of the director of public welfare and local registrar, Miami did not have one death from diphtheria among its own people during 1931, the first time this record has been attained since Miami began the compilation of statistics. The report says that a resident of Coral Gables, an adjoining city, came to Miami and died within a few hours of diphtheria.

Society News.—A recent meeting of the Volusia County Medical Society was addressed by Dr. Hugh West, DeLand, on hyperthyroidism, and Dr. Charles A. Clemmer on arteriosclerosis.——The Pinellas County Medical Society was addressed, Dec. 3, 1931, at Clearwater, by Drs. Louis M. Orr, Jr., Orlando, on "The Urologist and the Practice of Medicine," and Gaston H. Edwards, Orlando, on "Relationship of the Practitioner to the County Society and the State Association."

ILLINOIS

Society News.—Dr. William K. McIntyre, St. Louis, addressed the Adams County Medical Society, Quincy, February 8, on "Cancer of the Large Intestine."——Dr. Andrew C. Ivy, Chicago, addressed the Peoria City Medical Society, February 2, on "Physiological Aspects of the Etiology, Symptoms and Treatment of Gastroduodenal Ulcer."——The La Salle County Medical Society was addressed, February 9, by Drs. Robert S. Berghoff, Chicago, on "Syphilis of the Heart," and Arno B. Luckhardt, Chicago, "Ethylene Anesthesia" and "Importance of Animal Experimentation in the Advancement of Medical Knowledge."——Dr. Edmund Andrews, Chicago, addressed the Will-Grundy County Medical Society at Joliet, February 10, on "Intussusception."

Chicago

Society News.—The Chicago Gynecological Society will be addressed, February 19, by Drs. Louis Rudolph and Andrew C. Ivy on "Internal Rotation of the Fetal Head: From the Viewpoint of Comparative Obstetrics," and Dr. Henry Schmitz, "Technic of Irradiation in Uterine Carcinomas."——At the meeting of the Chicago Roentgen Society, February 10, the speakers included Drs. Cassie B. Rose on "Unusual Periostitis in Children"; Roe J. Maier, "Malignancy Originating in a Paget's Disease," and Maurice I. Kaplan, "Giant Cell Tumor of Humerus That Responded to Deep X-Ray Therapy."——Dr. James E. Lebensohn, among others, will address the Chicago Ophthalmological Society, February 15, on "Radiational Cataract."——The Chicago Society of Allergy will be addressed, February 15, among others, by Drs. Samuel J. Taub and Harry S. Arkin on "Asthma Due to Ingestion of Yeast."

KANSAS

Society News.—The Wyandotte County Medical Society was addressed in Kansas City, February 2, by Drs. La Verne B. Spake on "Surgical Mastoid" and Lewis W. Angle, "Bilateral Phrenicectomy for Persistent Hiccups." The society will be addressed, February 16, by Drs. Don Carlos Peete and Donald N. Medearis, Kansas City, on "Diagnosis and Treatment of Syphilitic Aortitis" and "Artificial Feeding of Infants," respectively.——Dr. Leslie C. Bishop, Wichita, addressed the Ford County Medical Society, Dec. 11, 1931, on hysteria.——At the meeting of the Harvey County Medical Society in Newton, Dec. 7, 1931, Drs. Lloyd O. E. Peckenschneider and Vern L. Pauley, both of Halstead, spoke on septicemia and preoperative treatment of the prostate, respectively.——Dr. William R. Dillingham, Salina, addressed the Saline County Medical Society, Dec. 10, 1931, on "Treatment of Normal Breech Presentation." Dr. Earl L. Vermillion, Salina, was elected president at this meeting.——Dr. John M. McWharf, Ottawa, among others, addressed the Anderson County Medical Society, Dec. 22, 1931, on the past and future of medicine.——Dr. Fred B. Kyger spoke on "Some Problems in Obstetrics" before the Golden Belt Medical Society at Manhattan, January 7, and Dr. Harry C. Berger, Kansas City, Mo., on "Visceroptosis in Children."——A round table discussion on improvements in medical and surgical treatment during 1932 was a feature of the meeting of the Wilson County Medical Society, January 11.——Dr. Paul S. Mitchell, Iola, will address the Sedgwick County Medical Society, Wichita, February 16, on "A Perspective and Aims of Our Society," and John Parkhurst, D.D.S., Iola, will discuss "Medical Legislative Problems." The society was addressed, February 2, by Drs. Thor J. Jager and Ernest M. Seydell, Wichita, on "Vesalius" and "Mastoiditis—Practical Considerations," respectively.

KENTUCKY

Society News.—A symposium on neoplasms of the urinary bladder was presented at the meeting of the Jefferson County Medical Society in Louisville, January 4, by Drs. James R. Stites, diagnosis; John T. Bate, Jr., treatment, and Joseph A. Bowen, neurologic aspects. Dr. Frank P. Strickler addressed the society, January 18, on "Surgery of the Common Bile Duct."——Dr. Eslie Asbury, Cincinnati, addressed the Bourbon County Medical Society, January 22, on treatment of fractures.——Drs. Irvin Abell and Adolph O. Pfingst, Louisville, addressed the Harlan County Medical Society, Harlan, January 23, on "Retrodisplacement of the Uterus" and "Eye Complications Following Fractures of the Skull," respectively.——At the quarterly meeting of the Southwestern Kentucky Medical Society, Hickman, February 4, speakers were Drs. Thomas D. Moore, Memphis, on "Instrumental Correction of Prostatic Obstruction"; Robert Lyle Motley, Memphis, "The Heart in Health and Disease," and Tinsly R. Harrison, Nashville, "Diagnosis of Organic Heart Disease."

Bills Introduced.—S. 142 and H. 224, to amend the pharmacy practice act, propose to abolish the registration of assistant pharmacists. S. 198 and H. 321, to amend the pharmacy practice act, propose to abolish the registration of assistant pharmacists and to allow present registered assistant pharmacists to be licensed, without examination, as registered pharmacists. S. 141 and H. 223, to amend the pharmacy practice act, propose that the board of pharmacy shall meet at least semiannually on the second Tuesday of January and July, instead of once in three months, as the present law provides. S. 145 and H. 162 propose a new dental practice act. S. 217 and H. 448 propose to create a state board of hairdressing and cosmetology examiners. Licentiates of the proposed board would be enabled, among other things, "to remove superfluous hair from the body of any female person." S. 149 and H. 246, to amend the law relating to chiropractic, propose to raise to $3 the annual renewal fee required of chiropractors. S. 290 proposes to authorize the establishment at each of the state hospitals for the insane a training course for attendants. H. 391 and H. 392 propose to create a board of barber and beautician examiners and to regulate the practice of barbering and beauty culture.

MASSACHUSETTS

Bills Introduced.—H. 188 proposes to create a board of magnetic healers' examination and registration and to regulate the practice of magnetic healing, defined as "the science of reviving and producing life and circulation in the nerve system and cells, so as to heal all nerve affections." No educational qualifications whatsoever are to be required of applicants. H. 787 authorizes courts to declare a marriage void where either spouse has been incurably insane for five years or more.

Survey of Health Education Activities.—The first comprehensive survey of health education activities in Boston is being undertaken. This study will include the activities of the Boston Health Department, the schools, city medical institutions, private agencies and commercial groups. The work will be carried on under the supervision of the health education committee of the Boston Health League, of which Clair E. Turner, professor of biology and public health at the Massachusetts Institute of Technology, is chairman.

Society News.—Mr. James M. Curley, mayor of Boston, addressed the William Harvey Society, January 8, on "What the City of Boston Is Doing to Promote the Public Health."——The Watertown Physicians' Society was addressed, January 4, in Watertown by Dr. Benjamin Tenney, Jr., Boston, on "Some Common Obstetrical Problems."——"Diagnosis and Treatment of Gonorrhea and Syphilis" was the subject discussed by Drs. Nels A. Nelson, James Dellinger Barney, Austin W. Cheever and Arthur C. Pearce, Boston, before the Waltham Medical Club, January 7.——The Harvard Medical Society was addressed, January 12, by Dr. William F. Rienhoff, Jr., Baltimore, on "Some Experimental Observations on the Thyroid Gland."——Dr. Harry C. Solomon, Boston, addressed the Essex South District Medical Society, January 6, on "Modern Treatment of Syphilis." The society was addressed, February 10, by Drs. Lincoln F. Sise and Harry H. Germain on "Selection of the Anesthetic for the Patient and Operation."——The Norfolk South District Medical Society was addressed, January 7, by Dr. William Reid Morrison on surgery of the stomach.——Dr. Joseph H. Fay, Melrose, addressed the Middlesex East District Medical Society, January 13, in Melrose, on "Treatment of Hip Fractures." Dr. Kenneth L. Maclachlan, Melrose, spoke on "Anemia in Obstetrics."——The South End Medical Club was addressed, January 19, by Dr. Harry W. Goodall, Boston, on "Carcinoma of the Colon."

MINNESOTA

Physician Sentenced to Penitentiary.—Dr. Torsten Ohrbom, St. Paul, Dec. 24, 1931, began to serve a sentence of three years and six months in the U. S. Penitentiary Annex, Fort Leavenworth, Kansas. The *Journal-Lancet* states that Dr. Ohrbom was sentenced "for faking government morphine certificates and obtaining the dope for his own use."

Society News.—Dr. Charles N. Spratt, Minneapolis, addressed the Hennepin County Medical Society, January 10, on "Treatment of Eye Injuries." The society was addressed, February 10, by Drs. Walter H. Fink and Albert H. Parks, Minneapolis, on "Optic Nerve Changes in General Diseases" and "Economic Therapeutics," respectively.——Dr. Clifton F. McClintic, Williamsburg, W. Va., among others, addressed the

Rice County Medical Society, Dec. 16, 1931, on headaches.——The Red River Valley Medical Society was addressed, Dec. 8, 1931, by Drs. Lyle L. Brown and Joseph G. Parsons, both of Crookston, on "Presentation of Some Bone Lesions in Children" and "Management of Mastoiditis," respectively.——At the meeting of the Minnesota Academy of Medicine, February 10, the speakers were Drs. Kenneth Bulkley on "Rôle of Oxyuris and Trichocephalus in the Etiology of Appendicitis"; Archa E. Wilcox, "Extraperitoneal Cyst," and Arthur E. Benjamin, "Nasal Catheter Suction Treatment of Postoperative Vomiting, Pain and Dehydration."

Violation of Basic Science Law.—Carl Beyer, operator of the Beyer System Clinic, Minneapolis, pleaded guilty to practicing healing without a basic science certificate, January 18, and was sentenced by Judge Reed of the district court to pay a fine of $200 or serve sixty days in the Minneapolis workhouse. The defendant paid the fine. According to the state board of medical examiners, Beyer has for several years been operating the Beyer System Clinic and claiming a successful treatment for diabetes, gallstones and other ailments over the radio and in local newspapers. As a result of this advertising, a farmer living near Shafer took his 16 year old boy to the clinic for treatment for diabetes. He paid Beyer $325 cash in advance. The boy's condition did not improve, and the father, learning that Beyer was not licensed, complained to the medical board. Beyer was arrested, January 8, and released on $1,000 bail. He was for some time prior to 1914 in the "patent medicine" business in Winnipeg, Manitoba, according to the state board. He claims to be from Austria and to be a dietitian.

MISSISSIPPI

Bill Introduced.—S. 100 proposes to prohibit the use of the words "drug store," "pharmacy," "apothecary," or similar names in places where no registered pharmacist is employed.

NEW JERSEY

Bill Enacted.—S. 7, approved by the governor, February 1, authorizes cities which maintain no municipal hospitals to enter into contracts with any regularly incorporated hospitals located in said cities and to pay such hospitals a sum not exceeding one mill on every dollar of assessable property located in the said cities for the purpose of maintaining and caring for such indigent patients as may be sent to such hospitals by the order of designated city officials.

Personal.—Dr. Berthold S. Pollak, medical director of the Hudson County Tuberculosis Hospital and Sanatorium, Secaucus, was the guest of honor at a reception at the sanatorium, January 31, marking his twenty-fifth anniversary in that position.——The Bergen County Medical Society held its annual dinner, Dec. 3, 1931, in honor of Dr. William L. Vroom, Ridgewood, who had completed forty-three years of practice. Dr. Vroom discussed the history of medicine in the county.

Extension Courses in Medicine.—For the third successive year the Medical Society of New Jersey and the extension division of Rutgers University, New Brunswick, are cooperating in the presentation of a series of graduate courses for physicians. The courses are being given in fifteen of the twenty-one counties of the state and are adjusted to meet the wishes of the county societies. They consist of eight weekly lectures, the starting dates covering the period from December 3 to April 7. Lecturers thus far announced include many physicians from the staffs of New York medical schools. The first course began, December 3, at Newton, Sussex County, with a schedule of four lectures each on fractures and newer drug therapy. Other subjects which will be used according to the desires of the local society include neurology, gynecology, pediatrics, traumatic surgery, obstetrics, gastro-enterology and surgery. Twenty-four courses have thus far been arranged for the fifteen centers, with a likelihood of additional centers to be established and other courses to be added, according to an announcement from the university extension division.

Society News.—The Bergen County Medical Society has adopted a junior membership for the physician who has been practicing less than one year, with one fourth the regular annual dues.——The twenty-second annual conference of New Jersey Health Officials was held, February 5, at Trenton. Among the speakers was Carl E. Buck, Dr.P.H., field director of the American Public Health Association, New York, on public health administration by county health departments.——A symposium on obstetric subjects comprised the program of the Hudson County Medical Society, Jersey City, February 2, with the following speakers: Drs. Arthur W. Bingham, East Orange, Edward G. Waters and Samuel A. Cosgrove, both of Jersey City.——Dr. Henry B. Decker, among others, addressed the Camden County Medical Society, Camden, February 2, on recent advances in bacteriology.——Dr. Matthew White Perry, Washington, D. C., addressed the Atlantic County Medical Society, Atlantic City, February 12, on "Neglected Considerations Concerning Colitis."——Dr. Joseph Jordan Eller, New York, addressed the Monmouth County Medical Society, Long Branch, January 27, on "Diagnosis and Treatment of Malignant Lesions of the Skin."

Bills Introduced.—S. 47, to amend the dental practice act, proposes to permit the licensing of dental hygienists, who are to have the right "to mechanically remove calcareous deposits, secretions and stains from the exposed surfaces of the teeth and directly beneath the normal free margins of the gums and to polish the teeth" but are not to perform any other operation on the teeth or tissues of the mouth. S. 48 proposes to make it a misdemeanor for any person to secure medical and surgical treatment from any governmental or charitable hospital or institution, free or at reduced rates, by means of false representations with respect to his financial condition. A. 63 proposes to allow villages and townships, as well as boroughs and towns, to make appropriations to private hospitals. A. 68 proposes to permit cities having no city hospital to appropriate not exceeding $20,000 annually toward the maintenance of any private hospitals located therein. A. 72, to amend the workmen's compensation act, proposes to permit injured employees to select their own physicians. A. 73 proposes to create a board of barber examiners and to regulate the practice of barbering.

NEW YORK

New Cancer Laboratory.—A new biologic laboratory is being completed shortly at Springville, Erie County, for the State Institute for the Study of Malignant Disease, Buffalo. The building, which replaces an old structure, affords about 1,300 square feet of space on the main floor. It will house several thousand animals, chiefly mice, used in the experimental study of cancer. It will have facilities for chemical, microscopic and histologic work and for transplantation of tissue, injections and other procedures.

Health at Utica.—Telegraphic reports to the U. S. Department of Commerce from eighty-three cities with a total population of 36 million, for the week ended January 30, indicate that the highest mortality rate (25.4) appears for Utica and the rate for the group of cities as a whole, 11.5. The mortality rate for Utica for the corresponding week last year was 14.8 and for the group of cities, 15.1. The annual rate for the eighty-three cities for the four weeks of 1932 was 12, as against a rate of 14.4 for the corresponding period of the previous year. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have large Negro populations may tend to increase the death rate.

Bills Introduced.—S. 415 and A. 591, to amend the law requiring the licensing of private institutions for the treatment of the mentally deficient, propose that the commissioner of mental hygiene be authorized to license such institutions for a definite period. S. 450 proposes that all certificates of birth contain photographs of the finger prints of the mother and the foot prints of the child. S. 546 and A. 464, to amend the workmen's compensation act, propose, in effect, to make compensable any occupational disease contracted in any employment covered by the act. A. 584, to amend the workmen's compensation act, proposes, in effect, to permit an injured employee to select his own physician. A. 596 proposes to create a board of barber examiners and to regulate the practice of barbering.

New York City

Brickner Lecture.—Dr. Albert A. Epstein gave the second Walter M. Brickner Lecture at the Hospital for Joint Diseases, Tuesday, February 9, on "Surgery in the Diabetic."

Fifth Harvey Lecture.—Dr. Andrew C. Ivy, professor of physiology and pharmacology, Northwestern University School of Medicine, Chicago, will give the fifth Harvey Society Lecture at the New York Academy of Medicine, February 18, on "Factors Concerned in the Evacuation of the Gallbladder."

Perkin Medal Awarded.—Charles Frederick Burgess, Ph.D., chemical engineer, has been awarded the Perkin Medal for 1932 by the American section of the Society of Chemical Industry. This medal is presented each year to the "American chemist who has most distinguished himself by his services to applied chemistry," who is selected by a committee representing the Society of Chemical Industry, the American Chemical Society, the American Electrochemical Society, the American Institute of Chemical Engineers and the Société de Chimie Industrielle. Dr. Burgess, a native of Wisconsin, taught for a number of years at the University of Wisconsin. He is the inventor of a process for the electrolytic purification of iron and many other chemical processes dealing particularly with storage batteries. He devised an apparatus for sterilizing liquids with nascent chlorine which has been used in hospitals to treat infected wounds and by explorers for sterilizing drinking water. The Perkin medal was founded in 1906 at the time of the Perkin semicentennial celebration of the coal tar discoveries and was first awarded to Sir William Henry Perkin himself. The presentation to Dr. Burgess was made, January 8, at a dinner of the interested societies in New York.

OHIO

Society News.—Drs. Paul M. Holmes and Barney J. Hein, Toledo, addressed the Putnam County Medical Society, Ottawa, January 5, on diagnosis of pulmonary tuberculosis and fractures, respectively.——Drs. Charles E. Held, Akron, and Marion D. Douglas, Jr., Cleveland, among others, addressed the Union Medical Association of the sixth district, Canton, January 13, on "Diabetes Mellitus—A Definition" and "Backache of Gynecological Origin," respectively.——At a meeting of the Stark County Medical Society, Canton, January 12, Dr. Clarence H. Heyman, Cleveland, spoke on fractures of the hip.——Dr. Julien E. Benjamin, Cincinnati, addressed the Hempstead Academy of Medicine, January 11, on "The Increase in the Death Rate from Heart Disease in the Fifth and Sixth Decades."——Drs. George T. Harding III and Donald E. Yochem made addresses on "Narcolepsy" and "Diagnosis and Treatment of Pernicious Anemia," respectively, before the Columbus Academy of Medicine, January 11.——Dr. Albert D. Frost, Columbus, discussed "Cooperation of the Oculist with the General Practitioner" at a meeting of the Ross County Medical Society, Chillicothe, January 7.——Drs. Milton B. Cohen and Roy W. Scott provided the program of the Cleveland Academy of Medicine, February 19, speaking on "Use and Abuse of Drugs in Asthma" and "Recent Advances in the Problem of Vascular Diseases," respectively.——Pediatricians of Cincinnati organized the Cincinnati Pediatric Society, January 15, with Dr. Albert J. Bell as president and Dr. Harold F. Downing, secretary.——Dr. Alfred Worcester, Waltham, Mass., addressed the Cincinnati Academy of Medicine, February 1, on "Care of the Dying."——Dr. Paul A. O'Leary, Rochester, Minn., will address the Cincinnati Dermatological Society and the specialty section of the Cincinnati Academy of Medicine, February 29, on "Therapeutic Problems of Syphilis."——Dr. James M. Pierce, Cincinnati, discussed "Nausea and Vomiting of Early Pregnancy" before the Cincinnati Obstetrical Society, February 11.——Dr. Charles Goosmann, Cincinnati, addressed the Montgomery County Medical Society, Dayton, February 5, on "Mistakes in Microscopic Diagnosis of Tumors."

PENNSYLVANIA

Society News.—Dr. Howard T. Phillips, Wheeling, W. Va., held a dermatologic clinic at the meeting of the Washington County Medical Society, Washington, February 10.——Dr. Barton C. Hirst, Philadelphia, addressed the Dauphin County Medical Society, Harrisburg, February 2, on recent studies in the causes of sterility.——Dr. Herbert F. Gross made the annual presidential address of the Harrisburg Academy of Medicine, January 19, on intestinal obstruction.——Dr. Alfred Friedlander, Cincinnati, addressed the Medical Forum of Pittsburgh, February 13, on "Clinical Applications of Recent Studies on Reticulocytes."——Dr. John J. Buchanan delivered an address on "History of Urology in Pittsburgh" at the February meeting of the Pittsburgh Urological Association.——Dr. George H. Shuman addressed an open meeting of the Pittsburgh Slit-Lamp Society, February 8, on "Controlled Versus Haphazard Methods of Applying Oblique Focal Illumination in Ocular Diagnosis."

Philadelphia

Annual Thomas Lecture.—The annual B. A. Thomas Memorial Lecture of the Philadelphia Urological Society will be delivered, February 15, by Dr. William F. Braasch, Rochester, Minn., on "Clinical Data in Connection with Polycystic Kidneys."

Bequest to University.—A bequest of $2,500,000 to the University of Pennsylvania for the erection of a hospital and an equal amount for an endowment was made public, February 2, when the will of Frederic S. Pepper, Jr., was probated. Mr. Pepper, a cousin of former Senator George Wharton Pepper, directed that the hospital be erected when the principal and accumulated income from his estate reached $5,000,000. It is to be built as a part of the University of Pennsylvania Hospital, according to the will, and will be for the "free care and treatment of sick and injured persons."

Joint Surgical Meeting.—The Philadelphia Academy of Surgery held a joint meeting with the New York Surgical Society, February 10, at the University of Pennsylvania. The following program of papers was presented: Drs. John B. Flick, "Spirochetal Infections of the Hand"; Calvin M. Smyth, Jr., "Treatment of Compound Fracture"; Eldridge L. Eliason, "An Operation for Inferior Radio-Ulnar Dislocation"; Alexander Randall, "Prevention of Postoperative Calculus in the Urinary Tract"; John Gibbon, "Kerr Technic in Anastomoses of the Colon"; George M. Dorrance, "Push-Back Operation for Cleft Palate," and John Stewart Rodman, "Chronic Cystic Mastitis or Abnormal Involution."

Society News.—The Philadelphia health department has recently discontinued its weekly bulletin, *Healthfax*, after five years of publication, for reasons of economy.——Dr. Josef B. Nylin delivered the weekly postgraduate seminar of the Philadelphia County Medical Society, February 12, on "Water as a Therapeutic Agent."——Dr. Stanley P. Reimann addressed the Pathological Society of Philadelphia, February 11, on "Neoplasms as the Result of Inheritable Chromosome Alterations" and Drs. Harold J. Stewart and Carl J. Bucher presented a paper on "Pulmonary Asbestosis."——Mr. Alexander Fleischer, secretary, Philadelphia Child Health Council, among others, addressed the Philadelphia Pediatric Society, February 9, with "A Report upon the Study of the Need for Breast Milk in Philadelphia."

SOUTH CAROLINA

Bills Introduced.—H. 1351 proposes to create a board of chiropractic examiners and to regulate the practice of chiropractic, defined as "the science of palpating and adjusting the articulation of the human spinal column by hand only." S. 1124 proposes to provide compensation to employees for disability or death resulting from injury arising out of and in the course of their employments. Compensation is not to be accorded for occupational diseases nor are injured employees to be permitted to choose their own physicians.

SOUTH DAKOTA

University News.—The medical library of the late Dr. Frank A. Swezey, Wakonda, has been presented to the University of South Dakota School of Medicine by Mrs. Swezey. It comprises several hundred volumes, pamphlets and notebooks.

Society News.—Dr. Guy E. Van Demark, Sioux Falls, addressed the Watertown District Medical Society, recently, at Watertown on "Fractures of the Upper Extremity."——At the meeting of the Sioux Falls Medical Society, Dec. 8, 1931, Drs. Sidney A. Slater, Worthington, Minn., spoke on "International Post-Graduate Tour of Europe"; Thomas J. Billion, Sioux Falls, "Treatment of Hemorrhoids," and John B. Gregg, Sioux Falls, "Foreign Bodies in the Lung."——At the annual meeting of the Yankton District Medical Society, Dec. 15, 1931, Drs. Robert H. McBride and Joseph E. Dvorak, Sioux City, Iowa, among others, spoke on "Infectious Diseases of Children."

TEXAS

Annual Clinic.—The annual Fort Worth Medical and Surgical Clinic of the Tarrant County Medical Society will be held, February 23, in Fort Worth, with Dr. William Paul Holbrook, Tucson, Ariz., as the guest of honor. Dr. Holbrook will make an address at the annual banquet and give a clinic on arthritis. Other clinical presentations will be on heart disease, diverticulitis, cancer, disabilities of the foot, diabetes, acute intestinal obstruction, pulmonary tuberculosis, goiter, diseases of the eye, ear, nose and throat, and modern laboratory methods.

WEST VIRGINIA

Physician Sentenced.—Dr. Latta Arthur Crandell, formerly of Tioga, was recently sentenced to two years and six months in the United States Penitentiary Annex, Fort Leavenworth, Kansas, and committed, January 13. He pleaded guilty to a narcotic charge.

Society News.—Dr. William Wayne Babcock, Philadelphia, addressed the Ohio County Medical Society, Wheeling, February 5, on "Newer Methods in the Surgical Treatment of Certain Diseases of the Heart and Great Blood Vessels."——Dr. William C. D. McCuskey, Wheeling, addressed the Marshall County Medical Association, January 12, on "Management of Prostatic Obstruction."——Drs. Dorsey Brannan, Morgantown, and Reginald S. Rilling, Pursglove, addressed the

Monongalia County Medical Society, Morgantown, January 5, on the Aschheim-Zondek test for pregnancy and uterine hemorrhage, respectively.——Drs. Vincent T. Churchman and Walter W. Point, Charleston, addressed the Logan County Medical Society, Logan, January 20, on "Industrial Eye Injuries" and "The Average Normal Case in Obstetrics," respectively.——Speakers at the January meeting of the Mingo County Medical Society, Williamson, were Drs. Ray M. Bobbitt and Francis A. Scott, Huntington, on "Urological Symptoms" and "Derangements of the Knee Joints," respectively.——The Mercer County Medical Society held a symposium on pernicious anemia at its meeting in Bluefield, January 21.——The Kanawha County medical and dental societies held a joint meeting in Charleston, January 5.——Drs. Clint W. Stallard, Montgomery, and Joseph M. Spinks, Mount Hope, addressed the Fayette County Medical Society, Oak Hill, January 12, on "Purulent Arthritis" and "Treatment of Incomplete Abortion," respectively.

GENERAL

American Board of Obstetrics and Gynecology.—A written examination of the American Board of Obstetrics and Gynecology will be held in nineteen cities of the United States and Canada, March 26. An oral and clinical examination is scheduled, May 10, in New Orleans. Further information may be had from the secretary, Dr. Paul Titus, 1015 Highland Building, Pittsburgh.

Scholarship in Health Education.—The National Tuberculosis Association announces that a scholarship of $500 is available in the field of health education in the department of biology and public health at Massachusetts Institute of Technology, Boston. Applicants should have basic training in mathematics, physics, chemistry and biology. Awards will be based on the nature and quality of the previous academic work of the applicant, personality qualifications and need of the financial aid. Applications should be sent before May 15 to the Child Education Service, National Tuberculosis Association, 450 Seventh Avenue, New York. The scholarship will be awarded in June.

Warning Against Impostor.—It has been reported that a man who gives his name as "Dr. Phares" of Evansville, Ind., has recently been hitch-hiking in the Southwest, representing that he is trying to find a position as surgeon, and soliciting the help and sympathy of the medical profession. On receipt of this information, inquiry was made by telephone and it was learned that Dr. John W. Phares of Evansville is regularly at his post of duty in that city, being a member of his local and state medical societies, and a Fellow of the American Medical Association. The itinerant individual, first above referred to, therefore is evidently an impostor. He is described as being 50 years of age or more, fairly well dressed and a good talker. In at least one town he is said to have visited every drug store, trying to buy paregoric. The profession should beware of impostors. In case of doubt, it would be well to telegraph or write the American Medical Association.

Prevalence of Communicable Disease.—Smallpox has been reported from various parts of the Middle West in recent newspaper dispatches. The appearance of five cases in Kalamazoo, Mich., January 16, led the health officer to order all students of the Woodward Avenue School to be vaccinated. Three virulent cases reported in a settlement near Richmond, Ky., January 15, caused the health officer to vaccinate all unprotected persons in the community. Twenty-four cases were reported at Anita, Iowa, January 2.——Twenty-three cases of measles were reported at Spring Lake, Mich., January 21.——In New York City, the health commissioner reported 1,700 cases of scarlet fever during January, with six deaths.——The weekly report of the U. S. Public Health Service for the week ended January 16 showed fewer cases of smallpox, poliomyelitis and meningococcus meningitis than for the corresponding week last year; almost the same number of cases of scarlet fever and measles, and increases in typhoid and diphtheria. In eighty-five cities there were 851 deaths from influenza and pneumonia, as compared with 1,530 for the corresponding week of 1931.

Society News.—The eleventh annual session of the American Congress of Physical Therapy will be held in New York, September 6-9.——Dr. Samuel McC. Hamill, Philadelphia, was elected president of the American Child Health Association at the annual business meeting, Dec. 10, 1931, in New York. Dr. Philip Van Ingen, New York, is secretary. President Hoover is now honorary president.——The next meeting of the Pacific Northwest Medical Association will be held in Spokane, Wash., June 27-29, with headquarters at the Davenport Hotel. The speakers will include Drs. Henry C. Bazett, Philadelphia; Samuel R. Cunningham, Oklahoma City; Harry Gideon Wells, Chicago; William J. Kerr, San Francisco; Philip H. Kreuscher, Chicago; Charles B. Wright, Minneapolis; Temple S. Fay, Philadelphia; Henry E. Michelson, Minneapolis, and Richard T. Atkins, New York.——The Catholic Hospital Association of the United States and Canada will hold its seventeenth annual convention at Villanova College, Villanova, Pa., June 21-24.——The American Orthopsychiatric Association will hold its annual meeting in Baltimore, February 18-20, with headquarters at the Lord Baltimore Hotel. A feature of the meeting will be a symposium on the contribution of psychology to the understanding of problems of personality and behavior.

Southeastern Surgical Congress.—The third annual assembly of the Southeastern Surgical Congress will be held in Birmingham, March 7-8, at the Tutwiler Hotel. The program will include addresses by Drs. William Wayne Babcock, Philadelphia, "Operative Treatment of Carcinoma of the Rectosigmoid with Methods for Elimination of Colostomy"; Edgar G. Ballenger, Atlanta, Ga., "Diagnosis of Surgical Affections of the Kidney and Ureter"; Vilray P. Blair, St. Louis, "Surgery of the Ocular Appendages and Related Structures"; Addison G. Brenizer, Charlotte, N. C., "Observations Drawn from 2,500 Thyroidectomized Cases with Special Reference to Hyperthyroidism and Hypothyroidism"; Willis C. Campbell, Memphis, Tenn., "Central or Intracapsular Fractures of the Neck of the Femur"; George W. Crile, Cleveland, "Technic and Clinical End-Results of Denervation of the Adrenal Gland"; Frank H. Hagaman, Jackson, Miss., "A Practical Treatment for Fractures of the Clavicle"; Carl A. Hedblom, Chicago, "Diagnosis and Treatment of Diaphragmatic Hernia with Special Reference to Selective Treatment"; Chevalier Jackson, Philadelphia, "Cancer of the Larynx"; C. Jeff Miller, New Orleans, "Gynecologic Backwash of Obstetrics"; Fred W. Rankin, Rochester, Minn., "Diagnosis and Treatment of Carcinoma of Rectum and Rectosigmoid"; Edwin Laurence Scott, Birmingham, "Surgical Care of Infantile Paralysis"; Walter Simpson, Dayton, Ohio, "Surgical Aspect of Undulant Fever," and George T. Tyler, Jr., Greenville, S. C., "Avertin Anesthesia." The Southeastern Surgical Congress was organized, Jan. 7, 1930. The territory covered includes Alabama, Florida, Georgia, Mississippi, North and South Carolina and Tennessee.

Ten Years of Mental Hygiene.—The results of the educational work in mental hygiene carried on in recent years are seen in a nation-wide inventory of facilities for study and management of mental disorders outside of institutions, made public by the National Committee for Mental Hygiene. In 1920, mental hygiene and child guidance clinics were comparatively rare. The study just completed shows there are 674 clinics providing regular mental health service to the public in thirty-four states. Most of these have come into existence since 1922, when the National Committee for Mental Hygiene and the Commonwealth Fund first joined forces for the development of child guidance work. Of the 674 clinics listed, 232 are child guidance clinics and the others are mental hygiene clinics handling both children and adults. More than 50,000 children and 36,000 adults were treated for behavior disorders and mental problems during the past year. The child guidance movement, the report points out, has come to command a recognition peculiarly its own and a popularity that has placed it in the forefront of the whole mental hygiene movement. The committee believes that this expansion of mental hygiene facilities is contributing to the prevention of breakdowns necessitating admission to hospitals. A directory of these clinics compiled by the Commonwealth Fund, now in course of publication, will give complete information concerning their services and will also describe other mental hygiene activities in each state. A table showing the distribution of child guidance clinics in cities of more than 150,000 population is included in the committee's inventory. A rating was adopted on the assumption that for every 200,000 of population there should be at least one clinic having the combined full time service of a psychiatrist, psychologist and two psychiatric social workers. According to this rating, Worcester, Mass., has the largest pro rata service among the cities; it is credited with 130 per cent. San Francisco is the largest city in the United States having practically no child guidance service.

Medical Bills in Congress.—*Change of Status:* S. 1690 has been favorably reported to the Senate, with an amendment, providing medical care and hospitalization for members of the National Guard, Organized Reserves, Reserve Officers' Training Corps and citizens' military training camps who are injured or contract disease while engaged in military training. Hearings were held, February 4 and 5, by the Senate Commerce Committee, on S. 572, to provide that the United States shall cooperate with the states in promoting the general health of the rural population of the United States and the welfare and hygiene of mothers and children. *Bills Introduced:* Senator Bingham, Connecticut, has proposed an amendment to S. 3090, relating to medicinal liquor, which would permit a physician to prescribe beer for medicinal purposes. S. 3404, by Senator Broussard, Louisiana, to erect a veterans' hospital at or near New Orleans. S. 3410, by Senator Nye, North Dakota, to erect an administration building at the veterans' hospital, Fargo, N. D. H. R. 8626, by Representative Norton, New Jersey, to provide hospitalization and medical treatment at hospitals and relief stations of the United States Public Health Service for certain seamen. H. R. 8629, by Representative Overton, Louisiana, to erect a 250 bed addition to the veterans' hospital, Alexandria, La. H. R. 8680, by Representative Crail, California, to provide a uniform pension law for disabilities incurred in war service and granting pensions to certain soldiers, sailors, marines and nurses who served the United States in time of war. H. R. 8756, by Representative Connery, Massachusetts, to erect a veterans' hospital at or near Boston. H. R. 8760, by Representative Hastings, Oklahoma, to erect a 200 bed addition to the veterans' hospital, Muskogee, Okla. H. R. 8762, by Representative Hardy, Colorado, to recondition buildings at the veterans' hospital, Fort Lyon, Colorado. H. R. 8905, by Representative Fulbright, Missouri, and H. R. 8920, by Representative Johnson, Missouri, to define the term "willful conduct," as used in the World War Veterans' Act, to include only intentional self-inflicted injury or conduct engaged in for the purpose and with the intent of developing and causing injury or disease, or aggravation thereof, or causing recurrence of disease. H. R. 8921, by Representative Lichtenwalner, Pennsylvania, to erect a veterans' hospital in Lehigh County, Pennsylvania. H. R. 8924, by Representative Owen, Florida, and H. R. 7228, by Representative Reid, Illinois, to provide pension for contract surgeons.

CANADA

Trachoma Among Alberta Indians.—The provincial government has recently set forth new regulations for the control of trachoma among the Indians of Alberta. Any house in which a person suffering from trachoma is found and in which proper precautionary measures are not being used may be quarantined. If in the opinion of the board of health treatment is necessary, the board may appoint medical and nursing staffs to procure eradication of the disease from any area within the province, according to the regulations. It is said that on one reservation west of Calgary almost one fourth of the population of 600 has trachoma. In view of the fact that the Indians travel constantly through other districts, this condition is considered a serious menace.

Hospital News.—The new St. John (N. B.) General Hospital was opened for patients, Oct. 16, 1931.——A new wing has recently been opened at St. Joseph's Hospital, London, Ont. It contains 115 beds, including a complete obstetric department, operating rooms for otolaryngology, a children's department and a laboratory suite.——Dr. Edleston H. Cooke, superintendent of the Alberta Provincial Mental Hospital, Ponoka, for twenty years, has resigned to engage in private practice. Dr. David L. McCullough, assistant superintendent, has been transferred to the provincial training school at Red Deer as acting superintendent. Dr. Charles A. Baragar is acting superintendent at Ponoka and Dr. G. A. Davidson of the Brandon Mental Hospital has been appointed to succeed Dr. McCullough.

Dr. Primrose Retires as Dean at Toronto.—Dr. Alexander Primrose, dean of the University of Toronto Faculty of Medicine since 1920, retired from that position, Dec. 31, 1931. Dr. Primrose first came to the University of Toronto in 1889 as demonstrator in applied anatomy. He was made associate professor in that department in 1892 and professor in 1896, a position he held until 1907. In addition he was made associate professor of clinical surgery in 1897 and professor in 1918, holding that chair until his retirement. Dr. Primrose served during the World War first as senior surgeon with the University Hospital unit and later as consulting surgeon to the Canadian forces in England. He is at present president-elect of the Canadian Medical Association. Dr. John G. Fitzgerald, professor of hygiene and preventive medicine, and director of Connaught Laboratories, has been appointed to succeed Dr. Primrose.

The Radium Treatment of Cancer

The medical research council has published the reports received from the various centers to which radium has been supplied from the National Radium Trust. Arranged according to localities, the principal results may be summarized as follows:

CANCER OF THE BREAST

At the Middlesex Hospital the best results were obtained with radium used at as great a distance as 6 cm. In the early stages, cancer of the breast appears to be unusually responsive to suitably planned surface radium therapy. At St. Bartholomew's Hospital there has been a tendency to irradiate more widely around the tumor. The patients who die succumb to distant metastases, and in almost all cases there has been great local improvement in or disappearance of the primary tumor.

CANCER OF THE UTERUS

In the treatment of cervical cancer, modifications of the Stockholm or Paris technics have been used. At the Royal Infirmary, Cardiff, fistula formation occurred in twenty-five cases. Expectation of life was longest in rectal, next in vesical, and least in double fistulas. At the London Hospital, where Radiumhemmet technic is followed, high voltage x-rays are used only for recurrence. When the parametria are invaded especially with fixation, the Marie Curie Hospital finds that supplementary external irradiation increases the number of five year cures. In the treatment of cancer of the body of the uterus the technic has been recently altered by giving smaller intra-uterine doses. Radon cylinders are placed in each cornu, radium tubes from fundus to internal os, and radium plaques in fornices. X-rays are given two weeks after treatment. Of forty-one patients treated since 1925, thirty-one are now living.

CANCER OF MOUTH, NOSE AND THROAT

At the Birmingham General Hospital it has been noted that the date and appearance of gland metastases bear no relation to the size of the primary growth. When the glands are enlarged and inoperable, the practice of removing part of a large mass followed by irradiation when the wound is healed has been abondoned. It is found better to expose the growth by reflecting skin and subcutaneous tissue and to insert needles. Since 1926, treatment has been given to 122 patients, with 43 clinical cures, 8 improved, 17 not improved, and 54 deaths. Clinical cures have been obtained in the following percentages: tongue (anterior two thirds), 32; (posterior two thirds) 24; floor of mouth, 15; cheek and lip, 52. In the throat the most hopeful sphere for radium proved to be extensive, septic, inoperable growths of the pharynx and hypopharynx which tend to invade the larynx. Radon was preferable to radium on account of the retching and discomfort provoked by the strings. Radon seeds were inserted around the growth and a radium collar was fitted, carrying needles parallel to the sternomastoid. Cancer of the esophagus has proved disappointing, but at University College Hospital one case showed improvement eight months after treatment.

CANCER OF THE RECTUM

At the General Hospital, Birmingham, fifty cases have been treated. Whenever possible, preliminary colostomy is performed. The usual technic is to remove the coccyx and lower part of the sacrum and insert needles around the growth, long needles being placed parallel to the mesorectum. Unsatisfactory results are attributed to the fact that rectal cancer is much more resistant than squamous epithelioma of the mouth. At St. Bartholomew's Hospital, intraperitoneal radon is given to the glandular area at the time of the colostomy. Attention is drawn to the possibility of inoperable cases becoming operable as a result of radium therapy.

CANCER OF THE BLADDER

At St. Peter's Hospital, out of fifty-eight patients twenty-eight had insertion of radon seeds by cystoscope and thirty open operation. In the latter a combination of diathermy and radium gave immediate relief. All the cases were advanced and none were cured, but symptoms were relieved for from six to eighteen months. It was found that a hemorrhage, however severe, could be controlled by a large dose of radiation of the whole malignant mass. For the prostate the technic of Herbst (suprapubic cystotomy and irradiation of the bladder base and prostate from within) was followed, but it is too soon yet to state its value.

BRAIN TUMORS

At the Royal Infirmary, Manchester, five cases of hemispherical glioma were treated by external radiation. Two of the patients are in good health and able to work, two are dead, and one is a complete invalid. It is concluded that gliomas are not especially radiosensitive and that the accurate placing of needles is difficult, as is the avoidance of structurally important areas at the boundary of the tumor.

SARCOMA AND LYMPHOSARCOMA

Good results were obtained in 50 per cent of cases of spindle cell sarcoma, in 41 per cent of round cell sarcoma and in 23.5 per cent of lymphosarcoma.

The Alcohol Problem

The royal commission appointed in January, 1930, to inquire into the working of the laws relating to the sale and supply of alcoholic liquors, to investigate the social and economic aspects of the question and to report on proposals for amending the law has presented its report, which has just been published. It constitutes a notable contribution to one of the most controversial social problems.

DECREASE OF DRINKING

A definite increase in the consumption of intoxicants occurred in the last twenty years of the nineteenth century, but the contrast between 1899 and 1929 is remarkable. In the former year the consumption of beer was 32.5 gallons a head; in the latter it had fallen to 16.4. The fall in the consumption of spirits was yet more remarkable—from 0.97 proof gallon a head to 0.25. Since the war there has been a rise in the consumption of wine, which is attributed to some extent to the increased duty on spirits, which now is five times as great as it was before the war. But it is considered that, despite the great improvement, excessive drinking still persists, and the commission is not satisfied that the situation can be sufficiently met by trusting to the general progressive tendencies of the age. It is noteworthy that of the 189 witnesses examined not one suggested that prohibition was a practicable proposition for this country. The demand was made before the commission that the inhabitants of newly developed areas should be given control of the licensing of saloons in their areas (a restricted form of what has long figured in the liquor controversy as "local option") and is favorably reported on.

The Curability Rate of Cancer

The great preponderance of cancer of the lip, tongue, mouth, pharynx and larynx in men and of the reproductive organs in women is pointed out in a report to the minister of health, by Dr. Janet E. Forber, on 2,000 hospital cases in East London. In a foreword the chief medical officer of the ministry, Sir George Newman, says: "The present report shows that if account be taken of the cases not submitted to treatment, the curability rate for all cases of cancer is about 21 per cent. These data strongly emphasize the need for educational effort *to secure that more patients in the early stage should avail* themselves of specialized treatment." In her report, Dr. Forber says that there is no shortage of medical or nursing care and that there was no delay of admission to a municipal hospital of any one who applied. There was no delay on the part of physicians in obtaining further advice and aid by referring the patients to hospital. The mean duration of inpatient care indicates that at least the final stages are seldom long, the mean duration being 2.28 months for all cases, under one month for 46 per cent, while only 7 per cent reached six months. There is some indication, contrary to the prevalent belief, that the duration is shorter in the aged.

Present State of Gold Therapy in France

Gold salts continue to be employed in France for the treatment of tuberculosis, especially the stationary and slowly developing types. One proprietary preparation is widely employed in the sanatoriums, but no one longer believes that it has a specific action on the Koch bacillus or that it exerts any other influence than to reinforce in a peculiar manner the defense of the organism against attacks, and indirectly facilitate spontaneous recovery by its own means. But gold salts, in their various forms, are used likewise in the treatment of lupus erythematosus, and articles by Pinard, Jeanselme and Burnier, Pautrier and Georges Levy, and Clément Simon, have announced numerous cases of amelioration and recovery—an average of about 60 per cent. All tests of the efficacy of gold preparations in leprosy have been fruitless. The trials were unfavorable also as carried out by Sézary, who reports that the use of gold in leprosy sometimes provokes an evolutive outbreak. Jansion observed in one case a rapid cachexia followed by death. Jeanselme and Burnier found gold absolutely inactive in leprosy patients. Better results were obtained in the treatment of syphilis, an old method applied formerly in France solely to syphilitic bone lesions. Levaditi's researches on the action of "Sanocrysin" in venereal spirochetosis induced experimentally in the rabbit, and the researches of Fournier and Mollaret, and of Jeanselme and Burnier, have been so favorable that gold, in the treatment of syphilis, has acquired a place alongside arsenic and bismuth. Jeanselme reports, as the result of "Sanocrysin" treatment, rapid cures of lesions that had resisted an intensive and prolonged arsphenamine treatment. Nevertheless, according to Jeanselme, gold does not render the Wassermann test negative so consistently as do arsenic and bismuth. Jeanselme suggests that gold treatment be reserved for cases of syphilis that have proved resistant to other medicaments. The results, moreover, have much improved since, following the example of Fournier and of Mollaret, oil injections have been employed. A precise indication is furnished by the coexistence in the patients of syphilis and tuberculosis. The latter evolves rapidly since treatment with mercury, arsenic or bismuth compounds has been instituted. In Lyons, Cordier and Gate found that in such patients oral therapy dispels all the syphilitic manifestations with remarkable rapidity, the evolution of tuberculosis not having exerted any influence, unless favorable. Interesting results have been secured in France also in the treatment of recurrent fever.

The Institute of Criminology

The Institute of Criminology in Paris has announced that on April 3 it will open a comprehensive course dealing with scientific police work, under the direction of Mr. Balthazard, pro-hygiene of mothers and children. *Bills Introduced:* Senator Bingham, Connecticut, has proposed an amendment to S. 3090, relating to medicinal liquor, which would permit a physician to prescribe beer for medicinal purposes. S. 3404, by Senator Broussard, Louisiana, to erect a veterans' hospital at or near New Orleans. S. 3410, by Senator Nye, North Dakota, to erect an administration building at the veterans' hospital, Fargo, N. D. H. R. 8626, by Representative Norton, New Jersey, to provide hospitalization and medical treatment at hospitals and relief stations of the United States Public Health Service for certain seamen. H. R. 8629, by Representative Overton, Louisiana, to erect a 250 bed addition to the veterans' hospital, Alexandria, La. H. Jeanselme reports, as the result of "Sanocrysin" treatment, rapid cures of lesions that had resisted an intensive and prolonged arsphenamine treatment. Nevertheless, according to Jeanselme, gold does not render the Wassermann test negative so consistently as do arsenic and bismuth. Jeanselme suggests that gold treatment be reserved for cases of syphilis that have proved resistant to other medicaments. The results, moreover, have much improved since, following the example of Fournier and of Mollaret, oil injections have been employed. A precise indication is furnished by the coexistence in the patients of syphilis and tuberculosis. The latter evolves rapidly since treatment with mercury, arsenic or bismuth compounds has been instituted. In Lyons, Cordier and Gate found that in such patients oral therapy dispels all the syphilitic manifestations with remarkable rapidity, the evolution of tuberculosis not having exerted any influence, unless favorable. Interesting results have been secured in France also in the treatment of recurrent fever.

The Institute of Criminology

The Institute of Criminology in Paris has announced that on April 3 it will open a comprehensive course dealing with scientific police work, under the direction of Mr. Balthazard, professor of legal medicine and dean of the Faculté de médecine, with the collaboration of Professor Claude, Associate Professors Piédelièvre, Duvoir and Sannié, hospital physicians Heuyer, Lévy-Valensi and Caillier, and certain high officials of the profecture of police. The course will consist of five parts: (1) legal medicine; (2) psychiatric legal medicine; (3) organization of police work; (4) legal and technical rules pertaining to judicial inquiries, and (5) evildoers and their habits and practices. This course will be restricted to persons who are enrolled at the Faculté de médecine. It is significant that many foreigners have registered for the course.

Vaccination Against Smallpox

Mr. Camus, head of the Institut vaccinal of the Academy of Medicine, has presented his annual report on the vaccinations performed in France and in the colonies, in 1930. This report is always delayed because it is necessary to work over a considerable number of documents, some of which are inadequately prepared. The year 1929, during which an epidemic of smallpox had threatened, was the occasion for vaccinations on a large scale. In 1930 there were 48,700 fewer vaccinations than in 1929. On the other hand, the revaccinations were more numerous in fifty-eight departments than in 1929. An increase of 33,721 revaccinations was noted, chiefly first revaccinations. This figure is explained in part by the increase in the birth rate for the year following the close of the war. The vaccine distributed was improved and gave more numerous positive results (takes). In the colonies, the vaccinations have been intensified in all regions. About 8,700,000 vaccinations were recorded for a population of 48,700,000. In Morocco 586,000 persons were vaccinated, and in Tunisia 759,000. In 1930 there was in all France only one case of smallpox and one case of varioloid. In recent weeks, however, there have been several cases of fatal smallpox at Tours. Morocco was apparently the source of the infection, several cases having developed at Montpellier, which goes to prove that there should be no relaxation in the matter of vaccination, even in France. In the colonies, smallpox is on the increase, in spite of the efforts of the health officers, whose task is not always an easy one (7,400 cases in 1929 as compared with 4,600 cases in 1928). In Indo-China the disease was widespread. In Morocco in 1929 there were reported 229 cases of smallpox as against 280 in 1930, and in Tunisia 61 cases in 1930 compared with 141 in 1929.

Meeting of International Association for Prevention of Blindness

The meeting of the Association internationale de prophylaxie contre la cécité was held recently in Paris under the chairmanship of Professor de Lapersonne. On the platform were observed Dr. Park Lewis, vice president of the association, representing the United States; Dr. Pantaleoni, delegate of the League of Nations; Professor Van Duyse of Belgium; Dr. Cridland, delegate from Great Britain; Professor von Grosz, Hungary; Dr. Van den Hoeve, Netherlands, together with representatives from Spain, Italy, Poland and Switzerland. Professor de Lapersonne announced the formation of new committees in the various countries. Dr. Coutela presented a paper on recent legislation and the prophylaxis of occupational eye accidents, and emphasized that this legislation does not provide adequately for the immediate treatment of the injured. Dr. Cridland, supported by Dr. Marquez (Spain), proposed that a comprehensive inquiry be made in all countries as to the most frequent causes of blindness and as to the best methods of prophylaxis. A resolution was unanimously adopted to this effect. Dr. Park Lewis delivered a lecture, illustrated by films, on certain rare types of parasitogenic cataract observed in fish. He pointed out that these observations invite more profound researches on the causes of human cataract.

Further Progress of the Lübeck Trial

In a recent letter (The Journal, January 30, p. 414), reference was made to accidents that resulted in Lübeck from the oral administration of tubercle bacilli, and to the progress of the trial being held in an effort to fix the responsibility. The taking of testimony of the experts has been practically completed. One can hardly be accused of dealing with an unsettled question if one reports on the present status of the trial; for the person who is far removed from the scene of action may lose touch with the trial, which has now lasted more than two months. The confusion is doubtless due to the fact that the apparently simple question, as to whether an unavoidable and unforeseeable accident, or negligence and a punishable technical error are involved, has been further complicated by the embarkation on discussions on the fundamental principles pertaining to tuberculosis; more particularly, to the Calmette B C G remedy. It was easy to foresee that a discussion of tuberculosis extending beyond the actual theme of the trial would lead to endless arguments.

Although eminent specialists in Lübeck explained everything that is known at present concerning the bacteriology and the epidemiology of tuberculosis, some of the participants at the trial insisted on summoning Calmette and other experts. Such a demand constituted an unjustified lack of confidence in the German experts. It is scarcely to be expected that a further clarification would result from an endless expression of opinions. The suggestion was made on the part of the general public that debates be held between the proponents and advocates of the various therapeutic methods. That would have led only to the presentation of various opinions, and every one would decide for himself which one he would approve; that is to say, the parties would have stood afterward in the same opposed relation to each other as before.

Even the opinions expressed in regard to the equipment and arrangements in the Pasteur Institute in Paris were at variance. A tuberculosis specialist among the Lübeck experts spoke disparagingly of the conditions that prevail in the institute, whereas the Berlin clinician Professor Leschke, in an article contributed to the *Medizinische Klinik*, declared: "The technic for the preparation of the vaccine was extremely precise and ingenious. It is well worth a visit to the Pasteur Institute and a study of the method, as the method is applicable to the preparation of other vaccines. The vaccine is prepared in a building especially designated for that purpose, into which none other than the B C G cultures are permitted to enter. The precautions taken go so far that the vaccine that was prepared in my presence was discarded because we had engaged in conversation while it was being prepared."

The bearing of Professor Deycke has made a deep impression. In view of the attacks of the prosecuting attorneys and the conditions that appear to be unavoidable in connection with a court procedure dealing with such questions, it was thought advisable for some one (the Berlin hygienist Professor Hahn assumed the duty) to make a statement, in the name of all the scientific experts present, in protection of the honor of Professor Deycke, to the effect that none of the experts had ever entertained the idea that Deycke had intentionally introduced virulent tubercle bacilli into the vaccine but that, on the contrary, the experts are all firmly convinced of the honorable character and veracity of Professor Deycke. The declaration was signed by Professors Abel, Bruno Lange, Ludwig Lange, Hahn, Kolle, Much, Uhlenhuth, Schurmann and Poll. Moreover, during the course of the trial, it became known, through a statement made by Deycke, that he carried out numerous experiments with tubercle bacilli on his own body. He injected into his person a pure culture of human bacilli of the Kiel strain, also human bacilli derived from a child and bacilli derived from other cultures, and made the observation that the reaction to the cultures derived from children was entirely different from the reaction to the Kiel strain. He presented several photographs in evidence of his statements.

Prof. Bruno Lange declared that transformation of the B C G vaccine into virulent tubercle bacilli was out of the question —that it was more likely that some confusion of the vaccine in the laboratory of the General Hospital had taken place. The cause of the confusion, which doubtless occurred between the end of October and the end of November, 1929, was presumably the absence of safety measures in connection with the vaccination in Lübeck. How the confusion arose cannot be established with certainty.

Geheimrat Abel of Jena, who was the last to give expert testimony, declared that he, in contradistinction to Professor Lange, was absolutely convinced, in accordance with the researches of Uhlenhuth, Seiffert, Much and others, that the affirmative assertion of Petroff with regard to the possibility of the B C G vaccine being split into virulent and avirulent bacilli is correct. In spite of the possibility of such a transformation, Abel gave his opinion that the greater probability pointed to a confusion in Lübeck, since it would be a remarkable coincidence if precisely in Lübeck such a destructive transformation of the B C G vaccine occurred and in no other place in the whole world. A further argument against such an assumption is the fact that sister cultures of the original culture sent to Lübeck had been used for the vaccination of thousands of children in France and Riga, without any transformation taking place.

These in part contradictory statements of the experts are cited only as an example. The opinions of the other experts were in part mutually corroborative and in part mutually destructive. Persons who are fully acquainted with tuberculosis research will not be surprised by the contradictory character of the testimony of the experts in regard to a spontaneous increase in the virulence of the cultures, the possibility of reversion from the avirulent to the virulent type, the harmlessness of the B C G vaccine, the significance of the culture mediums, or the employment of living bacilli. These questions are being constantly discussed in professional circles. They were likewise discussed in detail in Lübeck. But there is only an indirect connection between these questions and the real matter involved in the trial, which is concerned solely with the special arrangements in Lübeck and what occurred there.

A few weeks more will bring us to the fiftieth anniversary of Robert Koch's discovery of the tubercle bacillus. And although, in the course of this half century, the most eminent bacteriologists, hygienists and clinicians have devoted their lives to research on tuberculosis, there are still important differences of opinion with regard to the treatment. In fact, it is difficult to judge of the efficacy of a given form of treatment in any disease, and that is particularly true of tuberculosis. These facts serve to explain what may appear to be an unusual conflict of opinion in Lübeck. How the trial will end, no one can foresee, but when the final decision is reached, a report will be rendered here.

The Hygiene of Postage Stamps

Prof. F. W. Bach, the director of the Staatliches Medizinaluntersuchungsamt in Stade (Hanover), has carried out hygienobacteriologic researches on postage stamps. Postage stamps as they come from the press are practically germ free; but stamps bought in small amounts at the window have many more germs, some of which resemble Bacillus coli and others the streptococcus. The transmission of disease through postage stamps is not to be excluded, since disease germs may remain viable for several weeks; but such contamination need not be especially feared, particularly if the stamps are not moistened with the tongue. Nor are stamp collections especially dangerous, although it is not true that the benzine employed has any marked disinfecting action. In actual practice, in spite of widespread violation of hygienic rules in the handling of postage stamps, few evidences of infection have been observed.

Relationship Between the Hypophysis and the Thyroid

Professor Houssay and Drs. Magdalena, Biasotti and Mazzocco recently carried out experiments on the dog to find out the relationship of the hypophysis and the thyroid. They presented before the Sociedad Argentina de Biología of Buenos Aires a series of lectures on the results of their experiments. The removal of the thyroid produces hypertrophy of the hypophysis. The injection of the extract of the anterior lobe of the hypophysis causes hypertrophy and hyperfunction of the thyroid. The removal of the hypophysis is followed by the appearance of a typical change in the thyroid. The weight of the thyroid varied in the different groups of dogs used (dogs deprived entirely of the hypophysis and, as control, dogs in which a lesion of the tuber cinereum had been produced and dogs which were deprived either of the anterior or of the posterior lobes of the hypophysis). It was found that the thyroid of dogs entirely deprived of the hypophysis was the least heavy. Puppies deprived of the hypophysis show a retarded development of the thyroid. During the first days following either the complete removal of the hypophysis or a lesion on the tuber cinereum, the thyroid enters a phase of hyperactivity. Areas of colloid resorption with a pale aspect appear on the thyroid, and its follicular epithelium is very abundant. In dogs entirely deprived of the hypophysis the phase of hyperfunction of the thyroid is followed by hypofunction of the thyroid and atrophy of its epithelium. The fact that this type of atrophy does not occur either in dogs with a lesion of the tuber cinereum or in dogs that were subjected to ablation of the posterior lobe of the hypophysis shows that it is caused by insufficiency of the glandular portion of the hypophysis. During the first few days following the removal of the hypophysis the iodine content of the blood increases remarkably up to the forty-fifth or the sixtieth day, when it begins to diminish again until it reaches normal figures or slightly below. The iodine content of the thyroid gland of hypophysectomized dogs, calculated on 100 Gm. of the fresh thyroid gland, is lower than normal during the first thirty days following hypophysectomy; then it increases to figures higher than normal at the same time that the atrophy of the thyroid epithelium occurs. Subtotal thyroidectomy, when performed in dogs with a lesion of the tuber cinereum or in dogs deprived of the anterior lobe of the hypophysis, is followed by the appearance of a compensatory hypertrophy in the remaining part of the thyroid, with abundant production of follicular epithelium. This type of hypertrophy does not occur, however, when subtotal thyroidectomy is performed in hypophysectomized dogs. The speakers, having as grounds the results of their experiments, state that the hypophysis has a constant regulating action on the thyroid by which its normal anatomic functional condition is maintained. After hypophysectomy the thyroid gland enters a transient phase of histologic activity at the same time that the iodine content of the blood increases and the iodine content of the thyroid gland diminishes. The histologic hyperactivity of the thyroid during this phase is not a specific result of hypophysectomy, since it is also observed in dogs with lesions of the tuber cinereum. Later on, the thyroidal activity changes into a permanent phase of hypothyroidism with cessation of the histologic functions of the thyroid. During this period the iodine content of the thyroid increases, the iodine content of the blood diminishes, the basal metabolism is low (16 per cent lower than in control dogs), and a prolonged aqueous diuresis appears. The symptoms corresponding to this period are specifically caused by the absence of the anterior lobe of the hypophysis removed at total hypophysectomy. Hypothyroidism is directly caused by insufficiency of the hypophysis.

Congress of Surgery

The third annual congress of surgery of Argentina met, Oct. 12, 1931, at the Facultad de Ciencias Médicas of Buenos Aires, under the chairmanship of Professor Romagosa of Cordoba. Members of the medical faculties of several universities of Argentina attended the congress. There was an exposition of surgical apparatus. The topics discussed were "Complications and Results in the Treatment of Fibromyoma of the Uterus," by Drs. S. Marino and A. J. Bengolea; "Treatment of Fractures of the Forearm," by Drs. A. F. Landivas and M. Ruiz Moreno, and "Cancer of the Large Intestine, Not Including Cancer of the Rectum," by Drs. O. Copello and A. Ceballos.

Meeting of Regional Pathologists

The seventh meeting of the Sociedad Argentina de Patología Regional del Norte was held recently in Tucumán, with a large attendance of local and foreign physicians. The meeting was organized by Dr. S. Mazza, head of the Misión Universitaria de Patología del Norte, with headquarters and laboratories at Jujuy. Professor Nicolle of Tunis spoke on the transmission of exanthematous typhus by rats in Mexico, Dr. Catanei of Tunis on blastomycosis, and Dr. J. A. Domínguez on the progress in medicine made by the natives of Central and South America before the Spanish conquest. Drs. Bonorino Udaondo and Maissa discussed radiologic diagnosis and treatment of diseases of the liver and spleen; Drs. Talice and Mackinnon of Montevideo, mycosis of the external ear; Drs. Mazza and Palamedi of Buenos Aires, Pinto of Rio de Janeiro, and Theodor of Jerusalem, diseases caused by Coccidioides; Dr. Mello of Nova Goa, diarrhea caused by Flagellata; Drs. Delamare and Gatti of Asunción, the presence of spirochetes in the pleural fluid; Drs. Mazza and Alvarado, radiology of the colon in dysentery; Drs. Mazza and Villagrán, mycetoma of the foot, and Drs. Niño and Vera y Vivoli, several types of mycosis. One of the speakers said that the negativity of native Mataco Indians to the Dick test points to their being immune to scarlet fever. Dr. Villagrán described the characteristics of a special type of dermatosis caused by the Urundel tree. Drs. Luna and Canal Feijóo of Santiago reported a case of autochthonous Brucella infection in Santiago. Dr. Mazza described his experiments of serial transmission of Trypanosoma cruzi into an armadillo. Dr. Romaña isolated the same organism from a weasel of the genus Didelphis paraguayensis and from a tatou. Several articles were presented on Trypanosoma infection in monkeys, birds, and also in some species of Andean rodents. Speaking on the treatment of malaria, Drs. Alvarado and Mazza advocated the use of plasmochin.

News of the Academy

The Academia de Medicina of Buenos Aires recently held a meeting in memory of the late Dr. E. Cantón. Drs. Marotta and Jorge were recently appointed professors of surgery of the Academia de Medicina of Buenos Aires to fill vacancies left by the late Prof. E. Cantón and by Dr. A. Gandolfo.

Drs. A. Navarro and L. Morquio of Montevideo were recently appointed honorary academicians of the Academia de Medicina of Buenos Aires.

Deaths

Dr. J. Llambías, director of the Instituto de Anatomía y Fisiología Patológicas of Buenos Aires, aged 62.

Dr. P. Arata, former head of the chemical laboratories of the Faculty of Medicine of Buenos Aires.

Hay Fever in New Zealand

Dunedin is overshadowed by a heavy cloud of grass pollen during the late half of December and throughout January and the early half of February. Exposure of pollen plates, and a field survey made by C. E. Hercus and M. N. Watt of the department of bacteriology, University of Otago, and reported in the *New Zealand Medical Journal* for December, 1931, show that the grasses chiefly responsible are, in order of pollinating, cocksfoot, Yorkshire fog, both perennial rye and Italian rye, crested dogstail, timothy, and brown top, the latter being practically the only grass pollinating during the latter half of the aforementioned period. Prior to the peak period the only important grasses pollinating are Poa annua, Poa pratensis, twitch, and sweet vernal; the latter is extremely abundant, a profuse pollinator, but happily its period of intense pollination is relatively short, a matter of some three weeks or so. In addition to the pollens already specified, pollens of poplar, ash, broadleaf, plantago, native birch, and manuka were deposited on the plates in fair abundance.

From a study made of cutaneous reactions in 529 patients, it was found that cocksfoot is the most important grass excitant. As regards pollens other than grasses, the most frequent excitants were acacia, wattle, maize, plantago, manuka, Pinus insignis and macrocarpa. An interesting observation was that the reactivity of the skin varies according to its texture. In several cases it was found that with the same extract a moderate positive reaction on the lower aspect of the forearm became a strongly positive reaction if the more delicate skin of the upper arm was used. For strictly comparable results the skin of the lower half of the forearm should therefore be avoided.

An ascertainable family history of hypersensitiveness was present in 80 per cent of cases. Though the importance of the hereditary factor is recognized in most cases of naturally occurring hypersensitiveness in man, it is not necessarily always operative. Several cases have come under notice in which the family history had been negative and contact with an excessive concentration of the specific excitant had apparently produced hay fever.

As regards the results of treatment, the authors state that an exact evaluation of the results of any form of treatment is always a matter of great difficulty. In endeavoring to assess the value of the specific treatment of hay fever, the usual difficulties are increased by the number of variable factors peculiar to this therapy. Such factors as the correct selection of the exciting specific agent, the constancy of the strength of the therapeutic extract, the time of treatment in relation to the appearance of symptoms, and the method and size of dosage must all be duly considered. With these considerations in mind it will be at once realized that the final assessment cannot be made until a large number of cases have been carefully studied over a period of years. The results of treatment are, on the whole, most encouraging. The fact that 102 of the patients have returned for further treatment is, in itself, an important indication that the treatment is of value. Fifty per cent of these have returned during three, four and five hay fever seasons. Out of a total of 286 patients, 94, or 32 per cent, were completely free from symptoms; 146, or 51 per cent, received considerable relief, and 30, or 10 per cent, moderate relief, whereas 16, or 5 per cent, failed to derive any benefit. Constitutional reactions occurred in 91, or 31 per cent, of the cases treated. The pollen asthmas have shown a higher percentage of complete relief from symptoms than the pure hay fever cases. The treatment was entirely preseasonal by either the slow or the intensive method, or partly seasonal and partly preseasonal, or purely seasonal. One course of treatment, however successful, would not produce a permanent immunity.

Chair of Obstetrics at University of Otago

Dr. Joseph Bernard Dawson, M.D., F.R.C.S., has been appointed professor of midwifery and gynecology in the University of Otago at a salary of £2,000 per annum. The newly appointed professor is 45 years of age and of British birth and education, having received his professorial training at the University of Birmingham and at St. Bartholomew's Hospital. After graduation from the University of London, he engaged in postgraduate studies in order to obtain the higher degrees in medicine and surgery. During this time he held a number of resident appointments in the Birmingham hospitals, the Children's Hospital, Brighton, and St. Mark's Hospital, London. Besides systematic courses of lectures in midwifery and gynecology, his duties will cover the medical control and supervision of the maternity hospital and of the practical teaching of obstetrics (including antenatal and postnatal clinics and teaching), and the duties, operative and clinical, attaching to the position of gynecologist to the Dunedin Hospital, including the practical teaching in the subject of gynecology. It is the wish of the Otago University council that Dr. Dawson should, as soon as possible, spend approximately six months in visiting and in studying the methods adopted in the more important obstetric institutions in Great Britain, Ireland, the continental countries (including Holland and Denmark), the United States and Canada.

Statistics on Poisoning

As a measure of the control exercised over the distribution of poisonous substances and as an index of the suicidal tendencies of the population (six million), it is of interest to review the Australian statistics on poisoning, as revealed in the report for 1930 of the Commonwealth statistician. Suicides by solid or liquid poisons (noncorrosive) have taken a sudden leap to 192 cases, comprising 148 in males and 44 in females. These figures compare with 113 and 32, respectively, for 1929. Suicides by corrosive substances totaled 79, of which 49 cases were in males and 29 in females. This group is also higher by 9 cases than the previous year's total. Suicide by poisonous gas seems to have developed an alarming popularity. In 1927 there were only 16 cases from this cause. The following year twice as many such cases were recorded, and in 1929 there was a further increase to 37. Finally, 1930 shows a sharp rise to 58. Poisoning by food accounted for 21 deaths, as against 27 in 1929, and venomous bites and stings were responsible for 17 deaths, as compared with 14 cases in the previous year. Accidental absorption of irrespirable or poisonous gas was fatal in 25 cases (2 more than in 1929 and 14 less than in 1928). Accidental poisonings, happily, show a decline. The 1930 total of 63 deaths under this heading contrasts with 76 in 1929 and was made up of 47 males and 16 females. While there is apparently a decrease in the number of accidental poisoning cases, suicides show a marked upward tendency. There is a possible connection between these deaths and the state of trade and industry. The ages of suicides ranged between 15 and 80 years in the case of males, and between 13 and 64 years for females. In 1929 the largest number came, both for males and for females, from those aged between 35 and 50. In 1930, however, the greatest number of male suicides occurred at ages from 35 to 60, whereas for females the ages dropped to between 18 and 24 years.

Marriages

John Lawrence Riker, New York, to Miss Helene Beaudrais of Yonkers, N. Y., January 30.

Wade Thomas Parker, Fayetteville, N. C., to Miss Elizabeth Sikes Blue, January 26.

Sydney Rosenthal to Dr. Zelda I. Marks, both of Newark, N. J., February 7.

Deaths

Burton Alexander Randall ⊕ Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1880; emeritus professor of otology at his alma mater, assistant demonstrator of histology, 1880-1882, and professor of ear diseases, 1891-1924; professor of otology at the graduate school of medicine; member of the American Laryngological Association and member and past president of the American Otological Society; eye and ear surgeon to the Episcopal Hospital, 1882-1891, Methodist Hospital, 1896-1901, and Children's Hospital, 1885-1905; joint author of "Photographic Illustrations of the Anatomy of the Ear," 1887, and "American Textbook of Diseases of the Eye, Ear, Nose and Throat," 1899; aged 73; died, January 4, of heart disease.

Howard Homer Bell ⊕ St. Louis, Mo.; University of Pennsylvania School of Medicine, Philadelphia, 1912; fellow of the American College of Physicians; formerly instructor in pathology, University of Alabama School of Medicine, Mobile, and instructor in laboratory diagnosis; at one time assistant in pathology, instructor in pathology, associate in bacteriology and associate professor of bacteriology, Washington University School of Medicine; served during the World War; aged 47; on the staff of St. John's Hospital, where he died, January 7, of internal hemorrhage, following an operation for gallstones.

Reginald R. Walker ⊕ Washington, D. C.; Georgetown University School of Medicine, Washington, 1900; professor of clinical otolaryngology at his alma mater; member of the Medical Society of Virginia and fellow of the American College of Surgeons; served during the World War; consultant in otology, rhinology and laryngology, U. S. Veterans Bureau Diagnostic Clinic; surgeon to the Tuberculosis and Episcopal Eye, Ear, Nose and Throat hospitals; chief of service, department of otolaryngology, Children's Hospital; aged 54; died, January 15, of typhoid.

Carl Donald Chapell ⊕ Flint, Mich.; Michigan College of Medicine and Surgery, Detroit, 1905; member of the Radiological Society of North America; past president of the Genesee County Medical Society; formerly county coroner; on the staffs of the Hurley Hospital, St. Joseph's Hospital and the Women's Hospital; aged 53; died, January 11, in the Graduate Hospital, Philadelphia, of carcinoma of the left antrum with metastasis to the cervical glands.

David Edward Hoag, New York; University of Maryland School of Medicine, Baltimore, 1896; member of the Medical Society of the State of New York; clinical professor of neurology, University and Bellevue Hospital Medical College and the New York Polyclinic Medical School and Hospital; served during the World War; on the staff of the Westside Hospital; aged 63; died, January 20, in the Norwegian Hospital, Brooklyn, of pneumonia.

Peter Henderson Bryce, Ottawa, Ont., Canada; University of Toronto Faculty of Medicine, 1880; L.R.C.S., L.R.C.P., Edinburgh, Scotland, 1880; past president of the American Public Health Association and formerly chief medical officer of the federal department of health and Indian affairs; aged 78; died, January 15, at sea, while on the way to the West Indies.

Roscoe C. Carnal, Orwell, N. Y.; University of Maryland School of Medicine, Baltimore, 1905; member of the Medical Society of the State of New York and the Medical Society of Virginia; aged 49; died, January 13, in the Crouse-Irving Hospital, Syracuse, of an injury received when he fell from a second floor window.

Aaron La Fayette Harlan ⊕ Alexander City, Ala.; Medical College of Alabama, Mobile, 1886; past president of the Medical Association of the State of Alabama; member of the state board of censors of Alabama; state senator and member of the city council; aged 70; died, January 5, of heart disease.

John Hoadly Berry ⊕ Athens, Ohio; University of Cincinnati College of Medicine, 1910; member of the American Psychiatric Association; past president of the Athens County Medical Society; superintendent of the Athens State Hospital; aged 48; died, January 18, in Gallipolis, following an operation for appendicitis.

Baxter Timothy Smelzer, Albany, N. Y.; Bellevue Hospital Medical College, New York, 1874; member of the Medical Society of the State of New York; formerly secretary of the state board of health and member of the state legislature; aged 79; died, January 17, of prostatic hypertrophy and myocarditis.

William Alexander Walters ⊕ Los Angeles; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1906; member of the Pacific Coast

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

AURICULAR FIBRILLATION AND USE OF DIGITALIS

To the Editor:—A white woman, aged 44, married, the mother of two children, has been apparently in good health with the exception of some slight shortness of breath on exertion. An accident occurred, consisting of falling down several steps, in consequence of which she sustained a shoulder dislocation and two fractured ribs. Simultaneously, auricular fibrillation occurred. Digitalization was immediately effected. Two weeks has already elapsed and the cardiac note has been persistently above 100, ranging from 100 to 110, despite massive doses of digitalis. Except for some slight cardiac enlargement there is no further pathologic change. There is a barely palpable mass in the right thyroid area, and I am making a diagnosis of toxic adenoma. Basal metabolism tests are not confirmative, several having been made. Chemical analysis of the blood and the Wassermann test both give negative results. What medication would you suggest to reduce the pulse? Digitalis, strangely, whether in small or in large doses, has absolutely no beneficial effect; if anything, the pulse becomes more rapid. From a medicolegal point of view, just what are the possibilities, assuming that there is insurance involved? Please omit name. M.D., New York.

Answer.—Auricular fibrillation does occasionally have its onset consequent on some traumatism, as in this case. In such cases it is always probable that there was some preexisting cardiac lesion predisposing to the fibrillation. In this case the history of shortness of breath, and the fact that there is enlargement of the heart, indicate previous cardiac damage. It is a possibility also that the fibrillation was present before the accident, without anything more in the way of symptoms than the slight shortness of breath, and that it was first discovered at the examination after the accident.

It is unusual for auricular fibrillation not to yield to the administration of digitalis. It is possible that the digitalis was below standard strength. It is possible also that the optimal dosage had been passed and that the increase in rate with increased dosage is due to an overdosage. The effects of digitalis follow a fairly regular sequence; first, but not always in the normal rhythm, a decrease in rate; then a decrease in conductivity; an increase in irritability with occasional premature ventricular contractions; with a further increase in irritability a coupled pulse consisting of a normal beat followed closely by a premature ventricular contraction; with still further increase in irritability an increase in rate, which may give an irregular pulse but tends to be regular, and then ventricular fibrillation and death. The coupled pulse is a danger signal, and the increase in rate means that the patient has had a large part of the fatal dose, sometimes 85 or 90 per cent.

With a normal metabolic rate it is improbable that the adenoma of the thyroid is of any significance.

A pulse of 100 or 110 is not in itself an indication for digitalis administration. The volume of blood delivered by the heart per minute at that rate may be greater in some cases than at a slower rate.

Graphic records should be made to determine the condition, and the reasons for the digitalis effects. (A normal mechanism with frequent premature ventricular contractions could readily be mistaken for auricular fibrillation and given a similar picture.)

Intracranial hemorrhage may give rise to obscure fever by stimulation of the heat center. It is true that this child showed a slight nystagmus, though it is difficult to ascribe this single symptom to a cerebral cause, without other confirmatory observations.

The temperature of infants is sometimes influenced by the application of external heat. This is particularly true of premature infants who are placed in heated incubators.

The last possibility is that the child might have acquired an infection, and this sometimes occurs even when the most painstaking care is bestowed on the infant and the treatment of the navel. Umbilical infection may be present without any local evidence of inflammation. When the infection enters the blood stream, fever is one of the most striking symptoms, and localization in any case obviously may occur. One would be inclined to hazard the opinion that, owing to the rapid and fatal termination in this infant, either an infection or a cerebral hemorrhage was responsible.

POSSIBLE REACTION AFTER SCARLET FEVER IMMUNIZATION

To the Editor:—During an informal conversation with a group of physicians a few days ago, the subject of giving scarlet fever toxin for the active immunization of children was brought up, and Dr. G. C. Bullington of this city stated that he had heard of two severe reactions which occurred in two children when they received their last dose. I am giving this treatment to two children and was prepared to start it with my own child. Before going any further, I wish to ask whether you consider the hazard great, as I should be much distressed should anything happen to a child whom I was treating. I am using the Dick toxin that is marketed by E. R. Squibb & Sons. Louis H. Miller, M.D., Pana, Ill.

Answer.—Severe reactions following the fifth immunizing dose of scarlet fever toxin are rare. They have occurred in cases in which through mistake the fifth dose was injected first, without the preliminary immunization conferred by the injection of the first four graduated doses, but even in these cases they have not been fatal nor have they resulted in permanent injury. In the exceptional cases in which the patient is sensitive to broth, urticaria may develop within a few minutes after the injection of either scarlet fever toxin or diphtheria toxoid. This may be prevented by injection of 0.2 cc. of a 1:1,000 solution of epinephrine hydrochloride taken up in the same syringe with the immunizing dose, or the usual dose of epinephrine hydrochloride may be given when urticaria begins to appear. General reactions accompanied by some fever, nausea and rash are more apt to occur after the first, second or third doses than after the fifth.

Correspondence

THE STANDARD ENCYCLOPEDIA CORPORATION OF CHICAGO

To the Editor:—I don't know to what department I should address this letter, but I hope it may be put to use, so that it will warn other physicians against the book-agents I am describing.

A suave gentleman introduced himself into my office as the representative of the Standard Encyclopedia Corporation of Chicago and saying that he had been sent at the request of Doctor Walker (Chief of Medical Service, Brockton City Hospital) and Dr. George Moore (Secretary of Plymouth County Medical Association). He said his company had authorized him to make a gift of some of their publications to any new doctor just starting in this district, and that Drs. Moore and Walker had advised him to select me. I attempted to get these doctors on the telephone, but they were out. I listened to the clever talker—I am sorry I did not have a dictograph to take his misrepresentations for use in court—and he claimed that he was not a salesman but an advertising agent who was presenting me with certain volumes of books, etc., on condition that after receiving and approving them, I would permit his company to use my name in a sales campaign in this district to be carried on by a crew of boys under his charge. I told him I did not need any more *medical* books. He kept adding new inducements, such as free subscription to a Research Consultation Service, and motion pictures at half price. I asked to see the books and he showed me a prospectus with articles on insulin and other medical subjects, and I understood that the volumes he offered were Standard Encyclopediae of Medicine—since, I have learned that they are not medical books at all.

Having just started to practice medicine, I needed some medical books and I thought these must be good if Drs. Moore and Walker recommended them, so I told the man he might send them on for approval. He then suggested that if I would pay $2.50 monthly until a total of $69.50 had been paid, I would be entitled to ten years' extension service, which would keep the books up to date. So saying, he presented an order blank for me to sign. I refused until he said it was not a contract but was necessary in order that the books be sent for approval. I asked him what this item on the blank meant: "It is agreed that this order, when accepted by the publisher, is unconditional, not subject to cancellation, and will not be affected by any agreement not endorsed hereon," and he replied that the company would give me a chance to approve the volumes before accepting my order and that if I did not accept their offer, "it would be his hard luck" and I need not keep the books.

Well, I am young at the business and not used to book agents and the offer seemed fair, so I signed in order to get rid of him, and gave him $5 as a provisional payment. That evening I got in touch with Dr. Moore and Dr. Walker, and they were surprised and angry and denied having sent him. Dr. Moore had literally kicked him out of his office the previous day. I immediately wrote the Chicago office of the publishers, telling them the particulars and asking them to pay no attention to the blank their agent would be sending them, and not to send me the books or use my name in their advertising campaign. To my surprise, they replied I had signed a legal contract for $2.50 a month for a total of $69.50 and the books were on the express.

I refused the express and wrote them I had signed no contract. Also, I refused to sign an enclosure which they sent and asked me to confirm and approve the original order. They have since sent me several letters reproaching me for "lack of good faith and professional honor," etc., and insist on my "obligation."

Three days ago, I received a letter from their attorney—*John E. Roche, City State Bank Building, Chicago*—whom they have instructed to take steps to enforce collection. He states the full amount of $69.50 (less $5) is due. I have never made any monthly payments. He gives me until February 4 in which to pay, otherwise he will take court action and force me to pay court costs and attorney fees, in addition. However, he offers to oblige me by accepting a partial payment now, provided I meet the remainder by making four equal monthly payments.

Of course, I am consulting a local attorney, when he returns Monday.

I suppose I was quite gullible to listen to the agent, and showed lack of business acumen in signing any paper at all. I thought the man "on the level."

I am going into the above detail in hope you will make use of it, so that other new members of the profession may be warned and that the methods of the Standard Encyclopedia Corporation of Chicago be investigated. Any advice that you may give would be appreciated—especially if of use before February 4.

Herbert J. Hulse, M.D., Rockland, Mass.

[Editorial Note.—Dr. Hulse's letter, describing his experience with the Standard Encyclopedia Corporation and their agents, came after last week's Journal, that contained an article on this subject, was in the press.]

INFLAMMATION AS A DEFENSE MECHANISM

To the Editor:—In reference to the editorial in The Journal, January 9, on "Inflammation as a Defense Mechanism," in which you review my studies on the subject, may I call your attention to certain facts in regard to your comments in the last paragraph.

With Miriam F. Menkin (*J. Exper. Med.* **51**:285 [Feb.] 1930) I have shown that the accumulation of dye from the blood stream into an inflamed area is doubtless associated with increased capillary permeability, which is part of the acute inflammatory reaction. This was shown by measuring the rate of fall of concentration of trypan blue in the blood stream as it passes out into the inflamed and normal peritoneal cavity. The rate of fall of concentration of the dye in the blood stream is about twice as great in the capillaries of the inflamed area as in those of the normal area. This indicates that the accumulation of the dye from the blood stream into inflamed tissue is most likely associated with an increased permeability of capillaries. Furthermore, in a later study (*J. Exper. Med.* **53**:647 [May] 1931) I demonstrated that capillary permeability in inflammation is increased to the extent of allowing particulate matter to pass through the endothelial wall, a condition that is not seen in the capillaries of a corresponding normal tissue area.

In brief, the accumulation of foreign substances into an inflamed area from the circulating blood stream is explained mainly by the increased capillary permeability in the acute stage of inflammation, whereas the inability of these substances to escape from the inflamed area, i. e., their fixation in situ, is primarily the result of thrombosed lymphatics and of the presence of a network of fibrin at the site of inflammation, both of which cause mechanical obstruction to the normal lymphatic drainage of such substances from the tissue spaces.

For further reference, these points have been emphasized in a recent review "An Aspect of Inflammation in Relation to Immunity" (*Arch. Path.* **12**:802 [Nov.] 1931).

Valy Menkin, M.D., Boston.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

AURICULAR FIBRILLATION AND USE OF DIGITALIS

To the Editor:—A white woman, aged 44, married, the mother of two children, has been apparently in good health with the exception of some slight shortness of breath on exertion. An accident occurred, consisting of falling down several steps, in consequence of which she sustained a shoulder dislocation and two fractured ribs. Simultaneously, auricular fibrillation occurred. Digitalization was immediately effected. Two weeks has already elapsed and the cardiac note has been persistently above 100, ranging from 100 to 110, despite massive doses of digitalis. Except for some slight cardiac enlargement there is no further pathologic change. There is a barely palpable mass in the right thyroid area, and I am making a diagnosis of toxic adenoma. Basal metabolism tests are not confirmative, several having been made. Chemical analysis of the blood and the Wassermann test both give negative results. What medication would you suggest to reduce the pulse? Digitalis, strangely, whether in small or in large doses, has absolutely no beneficial effect; if anything, the pulse becomes more rapid. From a medicolegal point of view, just what are the possibilities, assuming that there is insurance involved? Please omit name.

M.D., New York.

Answer.—Auricular fibrillation does occasionally have its onset consequent on some traumatism, as in this case. In such cases it is always probable that there was some preexisting cardiac lesion predisposing to the fibrillation. In this case the history of shortness of breath, and the fact that there is enlargement of the heart, indicate previous cardiac damage. It is a possibility also that the fibrillation was present before the accident, without anything more in the way of symptoms than the slight shortness of breath, and that it was first discovered at the examination after the accident.

It is unusual for auricular fibrillation not to yield to the administration of digitalis. It is possible that the digitalis was below standard strength. It is possible also that the optimal dosage had been passed and that the increase in rate with increased dosage is due to an overdosage. The effects of digitalis follow a fairly regular sequence; first, but not always in the normal rhythm, a decrease in rate; then a decrease in conductivity; an increase in irritability with occasional premature ventricular contractions; with a further increase in irritability a coupled pulse consisting of a normal beat followed closely by a premature ventricular contraction; with still further increase in irritability an increase in rate, which may give an irregular pulse but tends to be regular, and then ventricular fibrillation and death. The coupled pulse is a danger signal, and the increase in rate means that the patient has had a large part of the fatal dose, sometimes 85 or 90 per cent.

With a normal metabolic rate it is improbable that the adenoma of the thyroid is of any significance.

A pulse of 100 or 110 is not in itself an indication for digitalis administration. The volume of blood delivered by the heart per minute at that rate may be greater in some cases than at a slower rate.

Graphic records should be made to determine the condition, and the reasons for the digitalis effects. (A normal mechanism with frequent premature ventricular contractions could readily be mistaken for auricular fibrillation and given a similar picture.)

CAUSES OF DEATH OF YOUNG INFANT

To the Editor:—Please give your opinion of the cause of death in the following case: November 17, I attended a woman in a normal confinement. The infant was apparently healthy and well in every respect. I visited the mother two or three days after the birth of the child, and both seemed to be in good condition. November 24, about 10 p. m., I was called to see the baby, which the parents thought did not seem "just right." The child had a rectal temperature of 105; there were no symptoms of a cold; the lungs were clear and the bowels in good condition; no cyanosis or spasms were present. A slight nystagmus was noted. The infant nursed all right and took water but died in the early morning, November 25. Please omit name.

M.D., Ohio.

Answer.—It is difficult in the absence of more detailed clinical data and a necropsy to state the cause of death. The most frequent causes of fever in the first days of life are transitory fever (thirst fever), overstimulation of the heat center, overheating and infection.

Transitory fever occurs between the second and the sixth day and is usually associated with continuous loss of weight. Children who are nursed, as this child was, and who receive sufficient water, rarely present the transitory type of fever.

Intracranial hemorrhage may give rise to obscure fever by stimulation of the heat center. It is true that this child showed a slight nystagmus, though it is difficult to ascribe this single symptom to a cerebral cause, without other confirmatory observations.

The temperature of infants is sometimes influenced by the application of external heat. This is particularly true of premature infants who are placed in heated incubators.

The last possibility is that the child might have acquired an infection, and this sometimes occurs even when the most painstaking care is bestowed on the infant and the treatment of the navel. Umbilical infection may be present without any local evidence of inflammation. When the infection enters the blood stream, fever is one of the most striking symptoms, and localization in any case obviously may occur. One would be inclined to hazard the opinion that, owing to the rapid and fatal termination in this infant, either an infection or a cerebral hemorrhage was responsible.

POSSIBLE REACTION AFTER SCARLET FEVER IMMUNIZATION

To the Editor:—During an informal conversation with a group of physicians a few days ago, the subject of giving scarlet fever toxin for the active immunization of children was brought up, and Dr. G. C. Bullington of this city stated that he had heard of two severe reactions which occurred in two children when they received their last dose. I am giving this treatment to two children and was prepared to start it with my own child. Before going any further, I wish to ask whether you consider the hazard great, as I should be much distressed should anything happen to a child whom I was treating. I am using the Dick toxin that is marketed by E. R. Squibb & Sons.

Louis H. Miller, M.D., Pana, Ill.

Answer.—Severe reactions following the fifth immunizing dose of scarlet fever toxin are rare. They have occurred in cases in which through mistake the fifth dose was injected first, without the preliminary immunization conferred by the injection of the first four graduated doses, but even in these cases they have not been fatal nor have they resulted in permanent injury. *In the exceptional cases in which the patient is sensitive to broth,* urticaria may develop within a few minutes after the injection of either scarlet fever toxin or diphtheria toxoid. This may be prevented by injection of 0.2 cc. of a 1:1,000 solution of epinephrine hydrochloride taken up in the same syringe with the immunizing dose, or the usual dose of epinephrine hydrochloride may be given when urticaria begins to appear. General reactions accompanied by some fever, nausea and rash are more apt to occur after the first, second or third doses than after the fifth.

SENSITIVITY TO SILK OR HOUSE DUST IN ASTHMA

To the Editor:—A white man, aged 28, a silk knitter, has been troubled with asthma for the past five years. The attacks are stubborn, often lasting a week or more and reacting poorly to hypodermic injections of epinephrine. They were first ushered in by attacks of migraine, with vomiting of bile, following which the bronchial spasm would develop. After biliary drainage and administration of autogenous vaccine prepared from the recovered bile, the attacks of migraine have ceased, but the asthma still continues. The patient has been completely tested for sensitivity to pollens, epidermals, foods, and bacterial and incidental proteins, the only positive result being a strong reaction to house dust. I have been unable to give him larger doses than 5 mm. of the solution prepared from dust from his home without instituting a severe reaction. The blood calcium was established and found to be 15 mg. per hundred cubic centimeters of blood. Examination of the nose and throat gave negative results. A tonsillectomy was done after scarlet fever six years ago. Following the suggestion of Rackemann, I had prepared an autogenous vaccine from the material coughed up from the lungs during the breaking up of an attack. This has the same effect as the dust vaccine. Feeling that the size of the dose of vaccine had perhaps been increased too rapidly, I started anew, attempting to repeat the dose until there was no longer any reaction. *This too has failed, because the patient repeatedly reacts* to the same dose, even to 0.025 cc. of dust extract, and to 2½ million bacteria in the autogenous vaccine. What suggestions have you to offer as to the further treatment of this case? Would you suggest calcium therapy, even though the blood calcium is high? In regard to calcium therapy, I have been led to believe that in cases of asthma and hay fever one may expect a lowered blood calcium. In another patient I found a blood calcium of 26.5 mg. per hundred cubic centimeters without any previous calcium therapy. This patient also had asthma. I am unable to find anything in my books *along these lines. Are the cases mentioned* instances of disturbed calcium metabolism? What is to be done in such cases? Please omit name and address.

M.D., Pennsylvania.

Answer.—The occupation of silk knitter suggests the possibility of silk as an exciting factor. Has this been *investigated* thoroughly? Is the patient better when away from his work? Are skin tests, cutaneous and intracutaneous, negative for silk? *If these are negative, a contact or patch test should be tried.* Some of the silk handled by the patient should be moistened with water and applied on a piece of gauze 1 inch square to a part of the back that has been cleansed with soap and water. The gauze should be covered with oiled silk, held by adhesive plaster and examined after twenty-four, forty-eight and seventy-two hours. A local dermatitis indicates a positive reaction.

If the silk can be excluded, further injections of house dust extract should be given. However, intracutaneous tests of 0.02 cc. each should be tried before the treatment is started; dilutions of 1:10, 1:100, 1:1,000 or even greater dilutions should be used, together with the undiluted extract; the dilution that just fails to give a reaction should be the one to be used; this will rarely cause any symptoms. These tests should be controlled by a test with physiologic solution of sodium chloride. The dose is gradually increased up to 1 cc.; the next higher dilutions are then used, in order, until, finally, undiluted extract can be given; it is an unusual individual who cannot eventually tolerate 1 cc. The blood calcium in asthma is probably not important. The earlier work showing low blood calcium has been disproved. Furthermore, giving calcium to asthma patients is rarely helpful.

TREATMENT OF COMPLICATED DIABETES

To the Editor:—I have under my care a woman, aged 65, suffering from diabetes complicated by a moderate arteriosclerosis and hypertension (150/90). She receives 20 units of U 40 daily. The urine is negative for sugar but shows many finely and coarsely granular casts with heavy traces of albumin. Chemical analysis of the blood gives negative results except for sugar, which is 285. The patient has a cataract of the left eye, completely obscuring her vision, and changes in the right retina due to the aforementioned conditions. She complains of dizziness as soon as she lies down, besides a constant noise in her head. 1. Is this dizziness due to the hyperglycemia, or is it in any way associated with the ocular condition? 2. Is there much risk in operating on a cataract in this case, the patient having had the diabetic conditions for five years and having been on insulin all this time? 3. Has it yet been determined whether this high blood sugar has any particular significance when the urine is negative for sugar? 4. What medication, if any, is indicated besides sedatives for the dizziness? 5 Is there any preparation that may be given orally that seems to benefit diabetes? If so, can it be given to replace insulin or used in conjunction with insulin? Please omit name.

M.D., New Jersey.

ANSWER.—1. It is doubtful whether hyperglycemia in itself produces dizziness. It must be recalled that this patient has arteriosclerosis, hypertension and signs of renal disease. The dizziness may be due to cerebral arteriosclerosis, or the ocular condition may have something to do with it. However, the fact that the dizziness bears a relation to position suggests an arterial basis.

2. A cataract operation should be practically without risk in this patient.

3. There is considerable doubt today as to the significance of such a blood sugar in an older patient with evidences of arterial and renal disease. Some authorities find a constantly high blood sugar in these old patients and do not pay a great deal of attention to it, as they consider that it may be due to a rise in the renal threshold. For this reason, and also because it has been shown that insulin is not entirely free from the danger of producing heart damage in such patients, some of the more recent investigators urge considerable caution in the effort to reduce hyperglycemia.

4. Potassium iodide, either alone or in combination with bromides, may be of considerable value.

5. No preparations given orally are of proved value in the treatment of diabetes. Synthalin, which has been given the most extensive trial, does seem to be beneficial in an occasional case, but Synthalin is far from being nontoxic and in some patients it produces liver damage. It seems best at present to use insulin and nothing else.

IRIDECTOMY IN CATARACT EXTRACTION

To the Editor:—A man, aged 60, in good physical condition except for early manifestations of paralysis agitans, contemplates surgical removal of senile cataract, unilateral. The patient's tonsils and teeth have been removed, and no focal infections are apparent. Is it advisable to have the iridectomy performed some time before the cataract is removed? If so, why, and what period usually is permitted to intervene between the operations? What is the prognosis so far as vision is concerned following the removal of the cataract, and what length of time is usually required after the operation before glasses may be fitted? Please omit name.

M.D., Ohio.

ANSWER.—The pros and cons in the question of preliminary iridectomy before cataract extraction cannot be discussed in the short space allotted to answers, and in a question of this type it is far better to rely implicitly on the operator and his experience in this matter. The more modern ophthalmologists no longer perform complete iridectomy in cataract extraction, thus eliminating the question entirely. When it is deemed advisable, the preliminary iridectomy usually precedes the cataract extraction by from four to eight weeks. Restoration of useful vision by cataract extraction is attained in about 96 per cent of the cases, provided the macular retina is somewhere near normal. Glasses are usually prescribed about six weeks after operation.

STERILITY DUE TO OBLITERATION OF DUCTS

To the Editor:—Kindly give possible effective treatment for male sterility due to obliteration of the ducts from old gonococcic infection. Please omit name.

M.D., Ohio.

ANSWER.—In the treatment of sterility due to an old gonorrheal infection, it is essential to diagnose ahead of time whether the absence of spermatozoa in the semen is due to the fact that the testicles no longer manufacture spermatozoa or whether it is due to an occlusion of both vasa which would prevent spermatozoa from entering the urethra because of occlusion of both vasa.

The diagnosis is made by inserting a rather large hypodermic needle into the testicle, aspirating some of the testicular fluid, and examining this fluid at once for spermatozoa. If these are found, the azoospermia is due to obstruction in the vas. In this case the only treatment that can possibly afford any relief is the operation of epididymovasostomy; namely, anastomosing the unoccluded part of the vas with another portion of the epididymis. Perhaps the best operation at present is that devised by Hagner (*Journal of Urology*, March, 1925, p. 377). The patient must, however, be definitely informed that, while without such operation there is absolutely no hope, the operation itself is only at times successful, though no harm can be done even if it does not succeed. Indeed, it may be repeated if unsuccessful the first time.

In case no spermatozoa are found in the aspirated testicular fluid, the operation is not indicated. One may administer extract of the anterior lobe of the pituitary gland, which at times brings back the spermatogenic function of the testicle. Later, condom specimens are examined and, if necessary, the testicle is again aspirated; if spermatozoa are found in the aspirated testicular fluid, the operation may be tried with some hopes of success. Of course, if spermatozoa are found in the condom specimen, nothing further need be done, as the diagnosis is established that the original azoospermia was not due to occlusion of the tubes but to deficient testicular action.

GRAVITY EDEMA WITH USE OF INSULIN

To the Editor:—What is the etiology of and treatment for a gravity edema that is apparently due to the use of insulin in a case of diabetes mellitus? Please omit name.

M.D., Pennsylvania.

ANSWER.—Joslin is authority for the statement that "Remarkable changes in the weight of normal individuals will . . . occur if the proportion of fat to carbohydrate is altered, although the caloric value of the diet remains constant." One gram of carbohydrate stored in the body demands the retention of 3 Gm. of water, while 1 Gm. of fat requires only 0.1 Gm. of water; therefore any condition which would improve carbohydrate storage simultaneously implies water storage. Insulin acts similarly by promoting storage of glycogen in liver and muscles, and this condition also means water retention. The effects of sodium chloride or sodium bicarbonate on edema and weight are well known, especially in diabetic persons.

Since marked edema explained on the basis of what has just been said has been known to occur in diabetic patients even before the use of insulin, it is probably true that the edema following insulin is due to improved carbohydrate utilization and storage. Regarding treatment, the sodium chloride intake should be analyzed to ascertain that the patient is not taking too much, and if alkaline therapy is being administered it should be stopped. Sometimes the edema can be made to disappear by starting with small doses and gradually increasing the insulin.

Further information may be obtained in an article by I. M. Rabinowitch (*Canad. M. A. J.* **17**:685 [June] 1927).

REACTIONS WITH DIPHTHERIA TOXOID

To the Editor.—One cubic centimeter of diphtheria toxoid (Lederle) produced a moderately severe reaction; i. e., soreness and edema of the entire upper arm. This persisted for four days. What results should be expected from a second similar injection, to be given one month following the first? Is there any method of modifying this type of reaction? Please omit name.

M.D., New York.

ANSWER.—A second injection one month after the first may cause a similar reaction. Such reactions may usually be avoided by injecting 0.1, 0.25, 0.5, 1, and 1 cc. of diphtheria toxoid at intervals of one week instead of from three to four weeks.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

Alaska: Juneau, March 1. Sec., Dr. Harry C. DeVighne, Juneau.

American Board of Obstetrics and Gynecology: Written examinations will be held in nineteen cities of the United States and Canada, March 26. The general, oral and clinical examination will be held in New Orleans, May 10. Sec., Dr. Paul Titus, 1015 Highland Building, Pittsburgh.

California: *Reciprocity.* Los Angeles and San Francisco, March 16. Sec., Dr. Charles B. Pinkham, 420 State Office Bldg., Sacramento.

Connecticut: *Homeopathic.* New Haven, March 8. Sec., Dr. Edwin C. M. Hall, 82 Grand Avenue, New Haven. *Regular.* Hartford, March 8-9. *Endorsement.* March 22. Sec., Dr. Thomas P. Murdock, 147 W. Main St., Meriden.

Maine: Portland, March 8-9. Sec., Dr. Adam P. Leighton, Jr., 192 State St , Portland.

Massachusetts: Boston, March 8-10. Sec., Dr. Stephen Rushmore, 144 State House, Boston.

National Board of Medical Examiners: Examinations will be held in cities where there are five or more candidates, Feb. 24-26. Ex. Sec., Mr. Everett S. Elwood, 225 South Fifteenth St., Philadelphia.

New Hampshire: Concord, March 10-11. Sec., Dr. Charles Duncan, Concord.

Oklahoma: Oklahoma City, March 8-9. Sec., Dr. J. M. Byrum, Shawnee.

Porto Rico: San Juan, March 1. Sec., Dr. A. Ortiz Romeu, Diaz Garcia Clinic, San Juan.

West Virginia: Charleston, March 22. Sec., Dr. W. T. Henshaw, Charleston.

Arkansas May Examination

Dr. Samuel J. Allbright, secretary, State Medical Board of the Arkansas Medical Society, reports the written examination held at Little Rock, May 12-13, 1931. The examination covered 12 subjects and included 120 questions. An average of 75 per cent was required to pass. Twenty-seven candidates were examined, all of whom passed. The following college was represented:

PASSED		
College	Year Grad.	Per Cent
University of Arkansas School of Medicine	(1931)	80, 80.4, 80.6, 80.8, 81.1, 81.4, 82.3, 82.4, 82.7, 83, 83.2, 83.8, 83.9, 83.9, 83.9, 84.4, 85, 85.2, 85.3, 85.4, 85.5, 85.7, 86.3, 86.8, 87.8, 88.3, 89.3

Kentucky Reciprocity Report

Dr. A. T. McCormack, secretary, Kentucky State Board of Health, reports 13 physicians licensed by reciprocity with other states and one physician licensed by endorsement of credentials from Aug. 10 to Dec. 28, 1931. The following colleges were represented:

LICENSED BY RECIPROCITY		
College	Year Grad.	Reciprocity with
University of Arkansas School of Medicine	(1931)	Arkansas
Indiana University School of Medicine	*(1927)*	Indiana
University of Louisville School of Medicine	(1929)	California
University of Maryland School of Medicine and College of Physicians and Surgeons	(1930)	Maryland
Harvard University Medical School	(1923)	California
Eclectic Medical College, Cincinnati	(1928)	Ohio
Ohio State University College of Medicine	(1928)	Ohio
University of Cincinnati Coll of Med.	(1929), (1930), (1931)	Ohio
Meharry Medical College	(1930)	Tennessee
University of Tennessee College of Med.	(1929), (1931)	Tennessee

LICENSED BY ENDORSEMENT		
College	Year Grad.	Endorsement of
Washington University School of Medicine	(1930)	N. B. M. Ex.

Alabama Reciprocity Report

Dr. J. N. Baker, secretary, Alabama State Board of Medical Examiners, reports 5 physicians licensed by reciprocity with *other states and one physician licensed by endorsement of credentials* from Sept. 10 to Dec. 15, 1931. The following colleges were represented:

LICENSED BY RECIPROCITY		
College	Year Grad.	Reciprocity with
Emory University School of Medicine	(1930)	Georgia
Graduate School of Medicine of the Division of Biological Sciences, University of Chicago	(1930)	Illinois
Tulane University of Louisiana School of Medicine	(1930)	Louisiana
Washington University School of Medicine	(1926)	Ohio
University of Virginia Department of Medicine	*(1926)*	*Virginia*

LICENSED BY ENDORSEMENT		
College	Year Grad.	Endorsement of
Johns Hopkins University School of Medicine	(1928)	N. B. M. Ex.

Medical Economics

THE PHYSICIAN'S INCOME TAX—1932

The taxpayer who is required to make a return must do so on or before March 15, unless an extension of time for filing the return has been granted. For cause shown, the collector of internal revenue for the district in which the taxpayer files his return may grant such an extension, on application filed with him by the taxpayer. This application must contain a full recital of the causes for the delay. Failure to make a return may subject the taxpayer to a penalty of 25 per cent of the amount of the tax due.

The normal rate of tax on individual citizens or residents of the United States, under the Revenue Act of 1928, is 1.5 per cent on the first $4,000·of net income in excess of the exemptions and credits, 3 per cent on the next $4,000, and 5 per cent on the remainder.

WHO MUST FILE RETURNS

1. Returns must be filed by every person having a *gross* income of $5,000 or more, regardless of the amount of his net income or his marital status. If the aggregate gross income of husband and wife, living together, was $5,000 or more, they must file a joint return or separate returns, regardless of the amounts of their joint or individual net incomes.

2. If *gross* income was less than $5,000, returns must be filed (*a*) by every unmarried person, and by every person married but not living with husband or wife, whose *net* income was $1,500 or more, and (*b*) by every married person, living with husband or wife, whose *net* income was $3,500 or more. If the aggregate net income of husband and wife, living together, was $3,500 or more, each may make a return or both unite in a joint return.

If the marital status of a taxpayer changed during the tax year, the amount of income necessary to bring him within the class required to make returns should be ascertained by inquiry of the local collector of internal revenue.

As a *matter of courtesy only, blanks for returns are sent* to taxpayers by the collectors of internal revenue, without request. Failure to receive a blank does not excuse any one from making a return; the taxpayer should obtain one from the local collector of internal revenue.

The following discussion covers matters relating specifically to the physician. Full information concerning questions of *general interest may be obtained from the official return blank* or from the collectors of internal revenue.

GROSS AND NET INCOMES: WHAT THEY ARE

Gross Income.—A physician's gross income is the total amount of money received by him during the year from professional work, regardless of the time when the services were rendered for which the money was paid, plus such money as he has received as profits from investments and speculation, and as compensation and profits from other sources.

Net Income.—Certain professional expenses and the expenses of carrying on any enterprise in which the physician may be engaged for gain may be subtracted as "deductions" from the gross income, to determine the net income on which the tax *is to be paid. An "exemption"* is allowed, the amount depending on the taxpayer's marital status during the tax year, as stated before. These matters are fully covered in the instructions on the tax return blanks.

Earned Income.—In view of the credit of 25 per cent allowed on *earned* net income, the physician should state accurately the amount of such income as distinguished from his receipts from other sources. *Earned income means professional fees*, salaries and wages received as compensation for personal services rendered. From this, in the computation of the tax, must be subtracted certain "earned income deductions." The difference is the "earned net income."

A physician may include as "earned" income money paid by patients who were looked after in part by his assistants. In order to do so, however, the patients on whose account the money was paid must have been in fact the patients of the physician-taxpayer and have looked to him as responsible for the services performed. Moreover, the services must have been performed under the physician-taxpayer's supervision.

The first $5,000 of an individual's net income from all sources may be claimed, without proof, to be *earned* net income, whether it was or was not in fact *earned* within the meaning set forth in the preceding paragraph. Net income in excess of $5,000 may be claimed as *earned* if it in fact comes within that category. However, a taxpayer may not claim, as *earned*, net income in excess of $30,000.

The conditions relating to the computation of the tax on earned income are too elaborate to be stated here. In case of doubt, physicians should consult collectors of internal revenue.

DEDUCTIONS FOR PROFESSIONAL EXPENSES

A physician is entitled to deduct all current expenses necessary in carrying on his practice. The following statement shows what such deductible expenses are and how they are to be computed:

Office Rent.—Office rent is deductible. If a physician rents an office for professional purposes alone, the entire rent may be deducted. If he rents a building or apartment for use as a residence as well as for office purposes, he may deduct a part of the rental fairly proportionate to the amount of space used for professional purposes. If the physician occasionally sees a patient in his dwelling house or apartment, he may not, however, deduct any part of the rent of such house or apartment as professional expense; to entitle him to such a deduction he must have an office there, with regular office hours. If a physician owns the building in which his office is located, he cannot charge himself with "rent" and deduct the amount so charged.

Office Maintenance.—Expenditures for office maintenance, as for heating, lighting, telephone service and the services of attendants, are deductible.

Supplies.—Payments for supplies for professional use are deductible. Supplies may be fairly described as articles consumed in the using; for instance, dressings, clinical thermometers, drugs and chemicals. Professional journals may be classified as supplies, and the subscription price deducted. Amounts currently expended for books, furniture and professional instruments and equipment, "the useful life of which is short," may be deducted; but if such articles have a more or less permanent value, their purchase price is a capital expenditure and is not deductible.

Equipment.—Equipment comprises property of more or less permanent value. It may ultimately be used up, deteriorate or become obsolete, but it is not in the ordinary sense of the word "consumed in the using"; rather, it wears out.

Payments for equipment or nonexpendable property for professional use cannot be deducted. As property of this class may be named automobiles, office furniture, medical, surgical and laboratory equipment of permanent value, and instruments and appliances constituting a part of the physician's professional outfit and to be used over a considerable period of time. Books of more or less permanent value are regarded as equipment, and the purchase price is therefore not deductible.

Although payments for equipment or nonexpendable articles cannot be deducted, yet from year to year there may be charged off against them reasonable amounts as depreciation. The amounts so charged off should be sufficient only to cover the lessened value of such property through obsolescence, ordinary wear and tear, or accidental injury. If improvement to offset obsolescence and wear and tear or injury has been made, and deduction for the cost claimed elsewhere in the return, claim should not be made for depreciation.

A hard and fast rule cannot be laid down as to the amount deductible each year as depreciation. Everything depends on the nature and extent of the property and on the use to which it is put. Five per cent a year has been suggested as a fair amount for depreciation on an ordinary medical library. Depreciation on an automobile would obviously be much greater. The proper allowance for depreciation of any property is that amount which should be set aside for the tax year in accordance with a reasonably consistent plan, not necessarily at a uniform rate, whereby the aggregate of the amounts so set aside, plus the salvage value, will at the end of the useful life of the property in the business equal the purchase price of the property or, if purchased before March, 1913, its estimated value as of that date or its original cost, whichever may be the greater. The physician must in good faith use his best judgment and make such allowance for depreciation as the facts justify. Physicians who, from year to year, claim deductions for depreciation on nonexpendable property will do well to make annual inventories, as of January 1, each year.

Medical Dues.—Dues paid to societies of a strictly professional character are deductible. Dues paid to social organizations, even though their membership is limited to physicians, are personal expenses and not deductible.

Postgraduate Study.—The Commissioner of Internal Revenue holds that the expense of postgraduate study is not deductible.

Traveling Expenses.—Traveling expenses, including amounts paid for transportation, meals and lodging, necessarily incurred in professional visits to patients and in attending medical meetings for a professional purpose, are deductible.

AUTOMOBILES

Payment for an automobile is a payment for permanent equipment, and is not deductible. The cost of operation and repair, and loss through depreciation, are deductible. The cost of operation and repair includes the cost of gasoline, oil, tires, insurance, repairs, garage rental (when the garage is not owned by the physician), chauffeurs' wages, etc.

Deductible loss through depreciation is the actual diminution in value resulting from obsolescence and use, and from accidental injury against which the physician is not insured. If depreciation is computed on the basis of the average loss during a series of years, the series must extend over the entire estimated life of the car, not merely over the period in which the car is in the possession of the present taxpayer.

If the automobile is used for professional and also for personal purposes—as when used by the physician for recreation, or used by his family—only so much of the expense as arises out of the use for professional purposes may be deducted. A physician doing an exclusive office practice and using his car merely to go to and from his office cannot deduct depreciation or operating expenses; he is regarded as using his car for his personal convenience and not as a means of gaining a livelihood.

What has been said with respect to automobiles applies with equal force to horses and vehicles and the equipment incident to their use.

MISCELLANEOUS

Laboratory Expenses.—The deductibility of the expenses of establishing and maintaining laboratories is determined by the same principles that determine the deductibility of other corresponding professional expenses. Laboratory rental and the expenses of laboratory equipment and supplies and of laboratory assistants are deductible when under corresponding circumstances they would be deductible if they related to a physician's office.

Losses by Fire, etc.—Loss of and damage to a physician's equipment by fire, theft or other cause, not compensated by insurance or otherwise recoverable, may be computed as a business expense, and is deductible, provided evidence of such loss or damage can be produced. Such loss or damage is deductible, however, only to the extent to which it has not been made good by repair and the cost of repair claimed as a deduction.

Insurance Premiums.—Premiums paid for insurance against professional losses are deductible. This includes insurance against damages for alleged malpractice, against liability for injuries by a physician's automobile while in use for professional purposes, and against loss from theft of professional equipment, and damage to or loss of professional equipment by fire or otherwise. Under professional equipment is to be included any automobile belonging to the physician and used for strictly professional purposes.

Expense in Defending Malpractice Suits.—Expenses incurred in the defense of a suit for malpractice are deductible as business expense. Expenses incurred in the defense of a criminal action, however, are not deductible.

Sale of Spectacles.—Oculists who furnish spectacles, etc., may charge as income money received from such sales and deduct as an expense the cost of the article sold. Entries on the physician's account books should in such cases show charges for services separate and apart from charges for spectacles, etc.

Book Notices

Simple Lessons in Human Anatomy. By B. C. H. Harvey, M.D., Professor of Anatomy, University of Chicago. Cloth. Price, $2. Pp. 434, with 234 illustrations. Chicago: American Medical Association, 1931.

The most lamentable ignorance exists not only among the general public but even among otherwise intelligent laymen concerning the structure and functions of the human body. This is the result of an educational system in which high school students learn much concerning the structure of crayfish and earthworms but next to nothing reliable about their own bodies. As a result, the most impossible theories, the wildest affirmations paraded as "facts," and all the fallacious but well contrived crudities of quackery are accepted without reservation as true by otherwise astute men and women. Any attempt to dispel the fog of mysticism and transcendentalism that, for the layman, enshrouds the human body is most commendable. Dr. Harvey's book is a remarkably successful attempt to bridge this Grand Canyon of ignorance. It is a popular presentation of a highly technical subject. In it anatomy is removed from its unpleasant associations with the dissecting room and its odors and gruesomeness and is made to live and to have "attractiveness for the average man." In the first seven chapters the structure and functions of the various tissues are presented. Then follow eleven chapters dealing with the different systems of the body. The last two chapters are entitled "Pharmacies within the Body" and "Life History of the Body." The presentation throughout is clear, and sufficiently simple and nontechnical to be readily understood by a reader of average intelligence. Apt analogies and literary and historical allusions will stimulate interest and aid understanding. "The Human Factory," a chart presented by special arrangement with Frankh'sche Verlagshandlung of Stuttgart and presenting "pictorially a very mechanical and simple idea of some of the important engines of the human body" is in keeping with the spirit of this machine age. The illustrations are well selected and add much to the usefulness of the text. The only significant criticism to be offered is that the organs pictured in some of the illustrations are burdened with their Latin or Greek names when their English equivalents might have been used. For example, in the illustration on page 198 appear the words "Hepar" and "Ventriculus." This volume should certainly be available for collateral reading and might well be used as a textbook in high schools and normal colleges. It can be safely recommended by physicians to their patients and will be a useful addition to the literature on the tables in their waiting rooms.

Handbuch der biologischen Arbeitsmethoden. Herausgegeben von Geh. Med.-Rat Prof. Dr. Emil Abderhalden, Direktor des Physiologischen Institutes der Universität Halle a. d. Saale. Abt. V: Methoden zum Studium der Funktionen der einzelnen Organe des tierischen Organismus, Teil 8, Heft 5: Funktionen des Kreislauf- und Atmungsapparates (Ergänzung zu Abt. V. Teil 4). Lieferung 359. Tonoszillographische Blutdruckmessung und die Deutung der Blutdruckkurve. Von Johann Plesch. Paper. Price, 4.20 marks. Pp. 773-844, with 37 illustrations. Vienna: Urban & Schwarzenberg, 1931.

The author describes an instrument for recording the blood pressure, the instrument, including the recording device, being housed in an air-tight metal box. The cuff contains a thin metal layer in the outer wall so as to direct all pressure inward, toward the artery. This cuff is equipped with a metal catch, so that it fits an arm of any size snugly. The "tonoszillogram," or record, that is made depends on two components: (1) the blood pressure proper, depending on the heart's contraction, and (2) the elasticity of the artery wall. Interpretation of the recorded curve was worked out by means of experiments with rubber tubes and tubes of gold beaters' leaf. The didatic notch and Kratham's sounds are discussed. Four phases of the record are described: 1. The compression phase, in which the outer pressure is greater than the maximum pressure plus the "compression pressure," so that the artery is flat. This phase may show oscillations caused by impacts of the pulse on the cuff. 2. The phase during which the outer pressure is less than the maximum pressure plus the "compression pressure" but greater than the maximum pressure. The end of this phase is the maximum pressure. 3. The third phase, during which the outer pressure is greater than the minimum pressure but less than the minimum pressure plus the "compression pressure." This phase ends with the minimum pressure. 4. The phase during which the outer pressure is less than the minimum pressure. For reading the record, the following characteristics are noted: 1. The "total minimum pressure" is that point at which the intervals between the individual oscillations cease and where the base points begin to appear. 2. The "total maximum pressure" is at the point where the first upstrokes of the pen appear. 3. The minimum pressure is at the point at which the inertia swing of the pen disappears and the artery acts less like an elastic tube. 4. The maximum pressure is the most difficult to read. The author found, by checking with auscultation, that the distance between total minimum and minimum pressure on the record is equal to that between the total maximum and maximum pressure.

Conquering Arthritis. By H. M. Margolis, M.D. Cloth. Price, $2. Pp. 192, with illustrations. New York. Macmillan Company, 1931.

Arthritis is by no means conquered. Scientific medicine has learned something about the nature of various forms of arthritis and, through trial and error or methods based on some knowledge of causation it has learned to help considerable numbers of those who suffer with rheumatic disease. The book is divided into chapters which trace the history and the classification of arthritis, give the cycles of the disease, state the distinction between the various forms, and describe the treatment. It becomes obvious at once to the reader that no one form of treatment is applicable to all cases but that the skilful physician will combine rest, exercise, diet, drugs, biologic methods, physical methods, surgical and orthopedic treatment and changes of climate in working out a formula that will be successful for the specific patient. The book is written in a form that can be followed by any intelligent reader.

Handbuch der normalen und pathologischen Physiologie mit Berücksichtigung der experimentellen Pharmakologie. Herausgegeben von A. Bethe, G. v. Bergmann, G. Embden und A. Ellinger. Band XVI, 2, Hälfte: Correlationen II/2: Correlationen des Zirkulationssystems, Mineralstoffwechsel, Regulation des organischen Stoffwechsels, die correlativen Funktionen des autonomen Nervensystems II. Bearbeitet von L. Asher, H. Eppinger, A. Fleisch, usw. Paper. Price, 78 marks. Pp. 1163-1860, with 73 illustrations. Berlin: Julius Springer, 1931.

In the present book (which completes volume XVI) are such sections as reflexes from the skin and various interoceptors on the heart and blood vessels, the effect of temperature on the circulatory system, hormonal influences on the circulatory system, effects of psychic processes on respiration, pulse rate, blood pressure and distribution of blood, the pathology of normal circulatory correlations, mineral content of and mineral metabolism in the body, regulation of organic metabolism by means of the nervous system and hormones, and the general physiology of the correlations occurring through the autonomic nervous system. Since the preceding half of the volume contains a section on the functional pathology of the vegetative nervous system and the correlations in the body effected by the endocrine glands, a long felt want for complete bibliographic reference to the physiology of the sympathetic and parasympathetic nervous system is now available. For just this type of reference handbook, clinicians (and psychologists) have been looking for some time. Since derangements in the autonomic system often express themselves in the form of sensory disturbances, clinicians are considerably more "conscious" of this important field than are laboratory workers.

Urological Roentgenology: A Roentgen Atlas of the Genito-urinary Tract with Case Histories and an Outline of Urology in Its Relations to Roentgenology. By Hugh H. Young, M.D., Clinical Professor of Urology, Johns Hopkins University, and Charles A. Waters, M.D., Associate in Clinical Roentgenology, Johns Hopkins University. Volume VII of Annals of Roentgenology. A Series of Monographic Atlases. Edited by James T. Case, M.D., Professor of Roentgenology, Northwestern University Medical College, Chicago. Second edition. Cloth. Price, $20. Pp. 564, with 592 illustrations. New York: Paul B. Hoeber, Inc., 1931.

Any one who criticized the first edition of this splended work could hardly fail to use superlatives. The second edition is amplified to include chapters on intravenous urography and anteriography. Chapter XI is devoted to intravenous urography and briefly takes up the history of the various compounds used in attempts to produce a usable, safe preparation for intravenous administration, these efforts culminating in the synthesis of what is known in Europe as uroselectan and in the United States as iopax. The authors give credit for this preparation to Binz and Raeth, Swick of New York and von Lichtenberg, in whose clinic the first satisfactory results were obtained. Excellent halftones illustrate this chapter. A conservative, accurate evaluation of the method is given. Chapter XII, on arteriography of the aorta and its abdominal branches in urologic surgery, contains quotations from the work of dos Santos, Lamas and Caldas and reproductions of eight of their films. Young and Waters "hesitate to express an opinion at this time on the startling work by dos Santos and his confrères." They have punctured the aorta in 150 cases without untoward results. This volume will serve as an excellent reference work to both the urologist and the roentgenologist.

Nutritional Anaemia in Infancy with Special Reference to Iron Deficiency. By Helen M. M. Mackay. Assisted by Lorel Goodfellow. With a statistical appendix by A. Bradford Hill. Medical Research Council, Special Report Series, No. 157. Paper. Price, 2s. Pp. 125. London: His Majesty's Stationery Office, 1931.

Secondary anemia is one of the most common disorders found in all types of environments and in all classes of people. It seems also that secondary anemia due to nutritional deficiencies is quite common as well. Anemia in infants brings an increased susceptibility to infections and for this reason must be combated early. This report is based on investigations lasting over five years on 1,100 infants. The studies seem to indicate that nutritional anemia is a clinical entity, and its etiology and prevention are considered. For prevention and cure, it is suggested that a child be given iron and ammonium citrate. It seems possible, however, that this preparation might better be saved for treatment and that foods high in iron content be given in the infant's diet as early as possible, as a preventive measure. The attention drawn toward the subject of anemia by this investigation will aid in promoting efforts for eliminating this disorder in infancy.

The Ingenious Dr. Franklin: Selected Scientific Letters of Benjamin Franklin. Edited by Nathan G. Goodman. Cloth. Price, $3. Pp 244, with 11 illustrations. Philadelphia: University of Pennsylvania Press, 1931.

This volume contains selected letters of Benjamin Franklin on a variety of subjects, many of them of medical interest. He wrote "Rules of Health and Long Life," an essay on choosing eye glasses, several essays on swimming, one on the treatment of gout, and a discussion of the causes of colds and their nature. These, together with many others on purely electrical and physical subjects, are included in the present book, which is beautifully printed and full of interest, not only for the Franklinophile but also for every intelligent reader.

Kochbuch für Tuberkulöse. Von Frau Mimicia Herrmansdorfer und Prof. Dr. med. et phil. Adolf Herrmannsdorfer. Mit einem Geleitwort von F. Sauerbruch. Fourth edition of „Praktische Anleitung zur kochsalzfreien Ernährung Tuberkulöser." Cloth. Price, 6.75 marks. Pp. 153. Leipzig: Johann Ambrosius Barth, 1931.

This contains recipes for the salt-free treatment of tuberculosis of the lungs and, where possible, of other parts of the body. There is a foreword by Professor Sauerbruch, who warmly recommends the dietetic treatment of Herrmannsdorfer by reason of having observed its beneficent effects on a large number of patients. The authors admit that it is a most difficult task to prescribe this diet for the tuberculous patient and make him like it. They say that only those who are sufficiently enthusiastic should undertake the work; that it requires constant supervision, sympathy and attention to the many details which are a constant concomitant of tuberculosis treatment. The book goes into the preparation of meals most minutely, so that any cook and physician can serve unsalted meals to finicky patients in an appetizing form. Unfortunately for some of the recipes, the ingredients are not always obtainable without breaking the prohibition laws. There are certain salts obtainable in Germany, probably proprietary, which seem to pinch hit fairly well for salt. Spices, flavors and sauces are used freely in order to overcome the lack of desirable saline taste. In connection with the salt-free diet, the authors urge the limiting of fluids, finding that in many cases the production of sputum is favorably influenced thereby. While the menus offered by the Herrmannsdorfers are most varied, they will in many cases need some revision before they can be used on American tables. This is not to be considered as an unkind criticism.

Allergy and Applied Immunology: A Handbook for Physician and Patient, on Asthma, Hay Fever, Urticaria, Eczema, Migraine and Kindred Manifestations of Allergy. By Warren T. Vaughan, M.D. Cloth. Price, $4.50. Pp. 359, with 37 illustrations. St. Louis: C. V. Mosby Company, 1931.

The number of books on allergy multiplies merrily. This is apparently the second good book on the subject prepared for both physicians and patients. It provides a comprehensive discussion of asthma, hay fever, urticaria, eczema and migraine. It begins with a discussion of the theory of anaphylaxis and allergy, its history, and its relationship to heredity and to other diseases. A second section deals with allergens in relationship to geographic location, animals, inhalants and foods. The third section deals with diagnosis and gives suggestions as to proper study of the history of the patient. Then comes a section on therapy from the point of view of desensitization and elimination of sensitizing substances. The final sections deal with prognosis, the manifestations of allergy and the relationship of allergy to immunology.

Physicians will find the book a most valuable reference, since it avoids highly technical considerations and deals with the practical aspects of the subject. Patients of college age will be able to follow the work and to realize value from it.

Einführung in die Bakteriologie oder Lehre von den Kleinwesen und ihren Wirkungen: Zum Gebrauch bei Vorlesungen und Übungen sowie zum Selbstunterricht für Ärzte, Tierärzte und Naturforscher. Von Prof. Dr. Walther Kruse, Direktor des Hyg. Instituts der Universität Leipzig. Second edition. Paper. Price, 13.50 marks. Pp. 436, with 78 illustrations. Berlin: Walter de Gruyter & Company, 1931.

This book follows conventional lines and does not show a novel point of view. It is clearly and concisely written and contains the usual material supposed to be desirable in the education of the medical student. Here and there one notices statements that are not well substantiated, such as that in the paragraph on page 55 in which staphylococci from pus are said to be susceptible of differentiation from other staphylococci by their agglutinative qualities. On page 226 it is stated that botulism poisoning through vegetable foods is much more common in America than in Europe on account of the frequent occurrence of the spores of the botulism bacillus in North American soil. The author seems to overlook the fact that the use of canned vegetables is more general in North America. The importance of contact infection in undulant fever (page 204) does not seem to be recognized. It does not seem likely that there will be any demand for a translation of this book into English.

Medicolegal

Examining Physician as Compulsory Witness Against Person Employing Him

(Webb et al. v. Francis J. Lewald Coal Co. et al. (Calif.), 297, P. 958)

One of the plaintiffs had been examined by a physician, apparently for the purpose of enabling him to testify on behalf of her and her husband in a suit for damages for personal injuries she had sustained. At the trial, however, the plaintiffs did not produce the physician as a witness. The defendants thereupon subpenaed him. When called to the witness stand, he refused to testify concerning his examination of the plaintiff or his conclusions from it. He contended that after a physician has made an examination for one party to a suit and his conclusions do not support the contentions of that party, and when he therefore has not been produced as a witness by that party, it would be inequitable to compel him to testify in support of the contentions of the adverse party. If it were known that a physician testified under such circumstances, patients would hesitate to come to him for examination and lawyers would hesitate to send their clients to him. The trial court ruled that the witness could not be compelled to testify. Judgment was given for the plaintiffs, and thereupon the defendants appealed to the district court of appeal, first district, division 1, California, assigning as error, among other things, the refusal of the trial court to compel the physician to testify.

This ruling of the trial court, said the district court of appeal, in reversing the judgment of the trial court, constituted reversible error. However commendable from a professional standpoint may have been the objections of the witness, the policy of the law as declared by the California legislature required him to set aside his scruples and to testify concerning the matters that he had learned from his examination of the plaintiff. When the party examined by him brought suit, she impliedly waived her right to have the results of the examination kept secret, for section 1881, subdivision 4, of the California Code of Civil Procedure provides:

> A licensed physician or surgeon cannot, without the consent of his patient, be examined in a civil action as to any information acquired in attending the patient, which was necessary to enable him to prescribe or act for the patient; . . . provided, further, that where any person brings an action to recover damages for personal injuries, such action shall be deemed to constitute a consent by the person bringing such action that any physician who has prescribed for or treated said person and whose testimony is material in said action shall testify.

If the ruling of the trial court were correct, said the district court of appeal, that the witness could not be compelled to testify unless arrangements were made to compensate him as an expert witness, it would in effect nullify the provision of the law just stated; for then, all a physician need do if he desired to keep off the witness stand would be to demand such compensation for testifying as it would be impracticable for the defendant to pay. That, said the court, is not the law.

> "The authorities, however, all agree that, in the absence of an express contract to pay a physician for his testimony as an expert, he is only entitled to the statutory fee. The uniform rule seems to be that a physician who has acquired knowledge of a patient or of specific facts in connection with the patient may be called upon to testify to those facts without any compensation other than the ordinary witness receives for attendance upon court. In those states recognizing the right to extra compensation for a physician who testifies as an expert it is uniformly held that, where such testimony is sought to be elicited without requiring any particular investigation on the part of the physician, he is required to testify without extra compensation."—*McClenahan v. Keyes, 188 Calif. 574, 583, 206 P. 454, 458.*

Workmen's Compensation Acts: Aggravation of Preexisting Cancer.—An employee was awarded compensation by the Oklahoma state industrial commission on a finding that he had sustained two distinct injuries in the course of his employment, which injuries aggravated a tumor which had existed or had its onset prior to the injuries. Since the last injury, the employee had been totally disabled from the performance of manual labor. It was insisted by the employer on an appeal to the Supreme Court of Oklahoma that the commission should have found that the employee's condition and his disability were the result of a natural cause, that is, cancer. A good deal of testimony, said the court, was taken on that line from medical experts, who disagreed as to the origin of the cancer and as to whether or not an injury could create a cancer or could aggravate one already created, whether latent or growing. The cause of cancer and its cure remain almost as much a mystery today as it did half a century ago, though men have devoted their lives to its study. Considering this and further that by statute, the industrial commission is the final judge as to questions of fact, it cannot be said that the evidence submitted to the commission did not warrant the finding that the injuries complained of aggravated a latent cancer.—*Magnolia Petroleum Co. v. Mayberry (Okla.), 297 P. 260.*

"Unsoundness of Mind"—Competence of Witness.—A Washington statute (Remington's Compiled Statutes, section 1213) declares that a person of "unsound mind" is not competent to testify, but it does not define the term "unsound mind." That term, said the Supreme Court of Washington, must include only those persons who are commonly called insane; that is to say, those suffering from some derangement of the mind rendering them incapable of distinguishing right from wrong. It cannot include the mere ignorant or uneducated, or those who are incapable of receiving all of the impressions within the comprehension of those more commonly gifted. It refers to those who are without comprehension at all, not to those whose comprehension is merely limited. Where the record indicates that a witness is uneducated and may show that he was easily persuaded to commit crime, yet if it clearly shows that he understood the criminality involved in the act to which he testifies and further shows that he was capable of giving a clear statement of the facts leading up to the crime and of the manner of its commission, he is a competent witness.—*State v. Hardung (Wash.), 297 P. 167.*

Malpractice: Physician Liable Only to the Extent of Aggravation of Preexisting Injury.—Where the plaintiff in an action for damages for malpractice has been suffering from a previous disability or infirmity, says the court of civil appeals of Texas, the trial court should take care to state clearly, fully and affirmatively to the jury that the plaintiff is entitled to recover only to the extent that his infirmity was increased or aggravated by the alleged malpractice of the physician-defendant. An injured employee has the right to maintain a suit for damages for malpractice against a physician furnished by the employer if the physician's malpractice has increased or aggravated the industrial injury, even though the employee had first proceeded and obtained compensation under the workmen's compensation law.—*Pedigo & Pedigo v. Croom (Texas), 37 S. W. (2d) 1074.*

Evidence: Delusions as Affecting Testamentary Capacity.—To destroy testamentary capacity, an insane delusion must be such as directly affects the testator in the making of his will and the disposition of his property. Where the delusions under which a testator labored were such as necessarily affected an intelligent and clear comprehension of his true relationship and situation as to his children, of what he had done for them and of his moral obligations to them, and were such as affected the testator's disposing judgment, the testamentary capacity of the testator has been destroyed.—*Erickson v. Lundgren (Mo.), 37 S. W. (2d) 629.*

Life Insurance: "Good Health" of Applicant Defined.—It is competent for the parties to a life insurance contract to stipulate that the contract shall not be deemed to be complete until the delivery of the policy and that it shall not be delivered unless the applicant is at the time in good health. "Good health" as used in such a stipulation is not apparent good health, nor yet a belief of the applicant that he is in good health, but it is that he is in actual good health. Slight troubles or temporary indisposition which will not usually result in serious consequences, and which do not seriously impair or weaken his constitution, do not establish the absence of good health, but if the illness is of a serious nature such as to weaken and impair the constitution and shorten life, the applicant cannot be held to be in good health.—*Klein v. Farmers' & Bankers' Life Ins. Co. (Kan.), 297 P. 730.*

Society Proceedings

COMING MEETINGS

American Association of Anatomists, New York, March 24-26. Dr. George W. Corner, University of Rochester School of Medicine, Rochester, N. Y., Secretary.
American Association of Pathologists and Bacteriologists, Philadelphia, March 24-25. Dr. Howard T. Karsner, 2085 Adelbert Road, Cleveland, Ohio, Secretary.
American College of Physicians, San Francisco, April 4-8. Mr. E. R. Loveland, 133 South 36th Street, Philadelphia, Executive Secretary.
American Orthopsychiatric Association, Baltimore, February 18-20. Dr. George S. Stevenson, 450 Seventh Avenue, New York, Secretary.
Annual Congress on Medical Education, Medical Licensure and Hospitals, Chicago, February 15-16. Dr. William D. Cutter, Secretary, Council on Medical Education and Hospitals, 535 North Dearborn St., Chicago.
Arkansas Medical Society, Little Rock, April 5-7. Dr. William R. Bathurst, 814 Boyle Building, Little Rock, Secretary.
Medical Society of the Missouri Valley, Omaha, Neb., April 5-7. Dr. Joseph D. McCarthy, 107 South 17th Street, Omaha, Secretary.
Pacific Coast Surgical Association, Santa Barbara, Calif., February 25-27. Dr. E. L. Gilcreest, 384 Post St., San Francisco, Secretary.

WESTERN SURGICAL ASSOCIATION

Forty-First Annual Meeting, held at Denver, Dec. 4-5, 1931

(Concluded from page 506)

Carcinoma of the Breast: A Critical Study of Twenty-Four Cases

Dr. Charles D. Lockwood, Pasadena, Calif.: In 1926 I began the routine postoperative use of radium in primary operable cases of cancer of the breast. I have followed essentially the technic of Handley but have used 12.5 mg. of unscreened radium needles, leaving them in for twenty-four hours. This gives a total dosage of 1,200 milligram hours. In a critical review of twenty-four cases, twelve of which were treated by operation alone, and an equal number in which the postoperative radium was employed, I am convinced that the cases treated with radium have given distinctly better results. All cases were in the operable group, most of them with axillary involvement. There were none in the very early favorable group and none in the hopeless advanced group. All were proved carcinoma cases by microscopic examination. Of the twelve patients treated by radical operation, and, with the exception of two, by postoperative roentgen irradiation, only four lived more than three years. All had recurrences. Of the twelve patients treated postoperatively with radium, seven are living and well three or more years after operation. In five of these there have been no recurrences. One patient lived for five years without recurrence and then a recurrence in the manubrium followed a severe blow on the chest. One recurred in the axillary glands. These were removed by secondary operation and radium again applied to the axillary region. The patient is living three years after the original operation, with no recurrence since the second operation.

Early Operation for Duodenal Ulcer

Dr. D. C. Balfour, Rochester, Minn.: The selection of cases for early operation would be greatly simplified if it were possible to predict with any accuracy the course of the disease in the individual case. As yet there are no satisfactory criteria on which to base predictions in the uncomplicated case. In the complicated case, that is, when the severity of symptoms or the radiation of pain indicates that extraduodenal involvement has occurred, or when there has been a massive gastro-intestinal hemorrhage, or when motor impairment can be demonstrated, early operation is clearly the best course for the patient to pursue unless it is definitely contraindicated. In the absence of such complications, I believe that there are certain conditions under which operation may properly be advised for early uncomplicated duodenal ulcer. The surgical treatment of the early duodenal ulcer must be in many respects conducted on different principles from the treatment of the more chronic, extensive and complicated lesions. There are three essentials in the surgical treatment of these early cases: The operation is of insignificant risk, it should give good prospects of permanent cure, and it should not interfere with future surgical treatment if ulcer develops subsequently. All three of these essentials usually can be met by direct attack on the ulcer and reconstruction of the pyloric outlet. Early operation for duodenal ulcer also permits removal of the appendix. Whatever the relationship between the appendix and the inflammatory conditions in the duodenum, it is safe to say that in such cases the patient has a better chance of permanent cure if the appendix is removed than if it is not. Operation will also give an opportunity for careful exploration of the abdomen and the exclusion of any other lesions that might have been a factor in the patient's complaint or a precursor of future disease.

Early Diagnosis of Acute Intestinal Obstruction

Dr. Owen H. Wangensteen, Minneapolis: The high mortality in acute intestinal obstruction is due in a large measure to late diagnosis. Factors that contribute to delay in diagnosis are the absence of local abdominal physical signs in simple obstruction; misinterpretation of the significance of the expulsion of gas with enemas; indiscriminate administration of morphine before making a diagnosis, and the equivocal and oftentimes deceptive information obtained with apparently effectual catharsis in partial obstructions. Intermittent colicky pain, associated with nausea and vomiting but unattended by abdominal tenderness or rigidity, suggests a block in the continuity of the bowel. In strangulation types of obstruction, local physical signs are usually present, though not as early as in peritoneal lesions of an inflammatory character. The bowel below the point of obstruction is physiologically as well as anatomically normal and will expel an administered enema with the return of gas and feces. Gaseous shadows in the small intestine demonstrate the presence of intestinal stasis. The stethoscope serves to distinguish whether the stasis is mechanical or paralytic in character. The general condition of the patient is not significantly altered in simple obstruction. In strangulation types there is often quickening of the pulse. Changes in the blood detected by chemical examination obtain regularly only in high intestinal obstructions and are a late occurrence. When the criteria on which the diagnosis can be made early are properly evaluated and patients with acute intestinal obstruction come to operation at an opportune hour, the appalling mortality of the disease will cease to exist. In dealing with the late case of simple obstruction, enterostomy, an indirect procedure and an operation of necessity rather than of election, should be practiced. Decompression of the bowel with the nasal catheter and water siphonage should prove to be a therapeutic agent of great value in many types of simple obstruction and especially in postoperative adhesive obstruction. In strangulation obstruction in which the bowel is not viable, exteriorization and excision with the temporary establishment of a complete fistula followed by secondary anastomosis is to be preferred to primary resection.

Effect of Distention of Bowel on Its Circulation

Drs. W. D. Gatch, John E. Owen and Harold M. Trusler, Indianapolis: We conclude from our experiments that intra-intestinal pressure above the diastolic blood pressure prevents absorption of toxin by way of the mesentery, and that intra-intestinal pressure below the diastolic blood pressure probably prevents or hinders such absorption. The possibility of absorption by this route following sudden release of pressure is left undecided. Any absorption of toxin from a bowel inflated by a pressure greater than the diastolic blood pressure must be transperitoneal. We have presented evidence which shows that absorption of the toxic material can take place through a fresh bowel wall rendered anemic by distention. Any absorption from a gangrenous bowel, or from a bowel having its mesenteric circulation blocked, must be transperitoneal. There is considerable evidence to show that the peritoneum in contact with obstructed bowel can react to prevent toxins from entering the circulation. The facts impress us in favor of the views that in strangulations of the bowel the chief route of absorption is transperitoneal, that the body has a fairly effective defense against this absorption, and that it occurs for the most part suddenly and shortly before death. The results of our experiments lent support to the view that the best treatment of advanced ileus is simple relief of obstruction either by means of a high Witzel enterostomy or by gun barrel enterostomy after resection of gangrenous bowel. The risk of leaving a gangrenous loop of bowel is often less than the risk of exploratory laparotomy. The ability of seminecrotic bowel to recover is phenomenal. Our experiments show that a rapid drop in blood pressure is the most constant indication that absorption of toxic material has occurred. We believe that this makes spinal anesthesia dangerous.

Chemical Aspects of Acute Intestinal Obstruction

Dr. Thomas G. Orr, Kansas City, Mo.: It appears from recent research that, by maintaining sodium chloride balance in the body in upper intestinal tract obstructive lesions, other chemical factors are also maintained in balance. This specific quality of sodium chloride is active in its fullest measure only when sufficient water is supplied to relieve or prevent dehydration. Distilled water and dextrose are not in any sense substitutes for sodium chloride solution in the treatment of obstructive or paralytic conditions of the gastro-intestinal tract.

Indications for Intestinal Drainage—Enterostomy and Colostomy

Dr. Donald Macrae, Council Bluffs, Iowa: I am convinced that no procedure has added more to the saving of life in my hands than enterostomy. One should not wait for fecal vomiting, or even near fecal vomiting in postoperative cases, or any other obstructive condition. I believe I was the first to advocate jejunostomy or enterostomy during the primary operation when there is the slightest evidence or anticipation of general peritoneal involvement developing after the operation. Drainage of all intussusception cases above the affected segment in every case, early or late, is, I believe, original with me. Many of my prophylactic enterostomy patients no doubt might well do without it, but the convalescence is so delightful to patient and surgeon, and the personal relief of knowing that one may not be required to perform a secondary operation, urge me to continue the practice. In addition, I am satisfied that, when more or less soiling of the peritoneum from early rupture of the appendix, for instance, is present, an occasional death from general infection may be avoided by draining the intestine.

Surgical Problems of the Thyroid

Dr. Arnold S. Jackson, Madison, Wis.: A discussion of the principal problems confronting the surgeon doing thyroid operations is given together with a summary of the data on these questions gathered from thirty members of the society. A comparison is also given from answers to questionnaires sent to the leading thyroid clinics. Among the problems considered is that of the iodine-fast exophthalmic goiter case in which it is pointed out that the risk of operation has been materially increased as a result of the prolonged use of iodine. Eighteen deaths as reported by those answering the questionnaires are cited as proof of this contention. The use of digitalis is discussed, also iodine in toxic adenoma. The advantages of the radio knife in performing thyroidectomy are stressed. A greater part of the goiter can be destroyed with a higher degree of safety and in a shorter time than with the scalpel. Postoperative progressive exophthalmos with hypothyroidism is discussed, also drainage after thyroidectomy; toxic goiter and pregnancy; radiotherapy; the postoperative use of iodine, and the decreasing incidence of toxic goiter.

Diagnosis and Surgical Treatment of Cysts of Thyroglossal Duct

Drs. Fred W. Rankin and Norman W. Crisp, Rochester, Minn.: Surgical extirpation of a cyst of the thyroglossal duct or a sinus of the thyroglossal duct is either a complete success or an absolute failure. There is no compromise in the estimation of results; few, if any, other operations of election have such an arbitrary prognosis. We have had little satisfaction in the confirmation of diagnosis by injecting the fistula with some opaque substance. Occasionally, in operating it has proved advantageous to inject methylene blue (methylthionine chloride, U. S. P.) into the tract, but since the technic used as a routine has given such satisfactory end-results this, too, has been abandoned. We have deviated little from the operative treatment as outlined by Sistrunk in 1920, the extirpation of the sinuses and cysts by this method being simple and satisfactory. Since Sistrunk's report, the number of consecutive cases of the cyst or sinus thyroglossal duct in the clinic has risen to 200. In more than 100 of these, operations, usually multiple, had been performed prior to the patient's admission; in one case as many as ten operations had been performed. The procedures had varied from incision and drainage, which, obviously, is indicated in the presence of acute inflammation, to curettement and incomplete excision. It was possible to do the complete operation in one stage in 175 of these 200 cases. In 9 cases in which acute infection was present, incision and drainage had to be done. In the 184 cases in which complete extirpation was done there has been no recurrence of trouble. In the remaining sixteen cases, because of extensive scarring and various degrees of infection, the tract could not be removed completely, but thus far recurrence of trouble has not been noted. However, further trouble may occur. One patient has returned recently who had been operated on before the Sistrunk operation was in vogue and apparently had been cured sixteen years ago. The duct then recurred, and its extirpation by the standard technic thus far has not been followed by recurrence or any evidence of failure.

The Pain of Tumors of the Spinal Cord

Dr. Winchell M. Craig, Rochester, Minn.: The history of pain is probably one of the principal features in the differential diagnosis between tumors of the spinal cord and lesions elsewhere in the body which produce similar symptoms. In a large percentage of cases, the symptom of pain is associated with some motor or sensory derangement which immediately gives a clue as to the nature of the underlying pathologic process. However, there are some cases of tumor of the spinal cord in which pain persists as the outstanding symptom for a number of months, or even years, proving so resistant to the more conservative forms of treatment that more radical measures seem imperative and, in the apparent absence of associated neurologic symptoms, operations on the abdomen or other regions are often carried out in the mistaken hope of relieving this pain. In reviewing a large series of cases of tumor of the spinal cord, it was found that such surgical procedures had been carried out in more than 10 per cent of the cases. Examples of these cases are presented in an effort to emphasize that, if the type of pain suggests that it may be of central origin, it is necessary to analyze the pain and to make repeated neurologic and other examinations, even in the presence of other coexisting pathologic changes.

Statistics of Appendicitis

Dr. Carl E. Black, Jacksonville, Ill.: In a table made up from fifty-two reports in standard surgical journals, an attempt was made to secure a basic average mortality in the several types of appendicitis cases. These reports were from more than 150 hospitals and comprised the work of more than 1,500 surgeons with 83,144 cases. While the results in the several categories varied from a mortality of 0.036 per cent in acute cases reported by Quain of Bismarck, N. D., to 42 per cent reported by Tucker of Wisconsin (Kirchner's cases from twenty-three hospitals), the final results may be summarized as follows: general mortality, 4.09 per cent; acute cases, 4.88 per cent; chronic cases, 0.99 per cent; suppurative cases, 10.15 per cent (or, omitting 10,000 cases by Kirchner covering a period of thirty years, 7.87 per cent); gangrenous cases, 8.73 per cent, and spreading peritonitis cases, 21.19 per cent. This summary furnished the basic average mortality figures for appendicitis. A comparison of these cases was made with my own statistical results from a study of the appendicitis cases from Passavant Memorial Hospital for nine years. In my group there were nine operators with an average mortality for the period of 4.88 per cent. By deducting the cases of one surgeon in my group, the mortality would be reduced more than 1 per cent.

Cautery Excision of Malignant Cervix Uteri After the Method of Wertheim

Dr. James F. Percy, Los Angeles: I duplicate the operation originally performed by Wertheim with the cold knife with one that has a cauterizing heat—not diathermy. The malignant growth in the vagina is first thoroughly cooked with the cautery so that the fixed pathologic areas are not only sterilized but made movable. The operation is then completed from the abdominal side, also with the cautery knife.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Diabetic Pyorrhea. J. B. Williams, Richmond, Va.—p. 807.
*Immune Transfusion in Lobar Pneumonia. A. L. Barach, with assistance of M. Soroka, New York.—p. 811.
Cholagogue Effect of Intravenous Injection of Sodium Dehydrocholate, with Résumé of Literature on Bile Salt Metabolism. R. F. Sterner, H. J. Bartle and B. B. V. Lyon, Philadelphia.—p. 822.
Survey of Diphtheria Prevention in Philadelphia. E. L. Bauer, Philadelphia.—p. 839.
*Clinical Observations on So-Called Leather-Bottle Stomach. J. Friedenwald and T. H. Morrison, Baltimore.—p. 847.

Hodgkin's Disease.—Krumbhaar reports the case history and necropsy observations in a fatal case of Hodgkin's disease that was practically limited to the spleen and bone marrow, though in these two organs the involvement was extensive. The histologic appearance of the femoral bone marrow suggested that the disease process may have been primary in this tissue. Absolutely no lymph node involvement could be found, and the lymphoid tissue of the gastro-intestinal tract was histologically unchanged. While this does not constitute unequivocal proof of the absence of lymph node involvement, it points strongly in that direction. The absence of lesions in the mucosae and of the so-called germinal centers in the spleen suggest interesting speculations as to the type of cell in which the disease process originates. The author suggests that the disease should be considered a disease of the hemolytopoietic or the reticulo-endothelial system rather than of lymphoid tissue.

Cardiac Pain and Sudden Death.—According to Lambert, the most frequent cause of sudden death is not cerebral hemorrhage but some cardiac lesion. Sudden death is not of common occurrence in heart disease when all forms of heart disease are considered. Pathologic anatomy does not offer an explanation of cardiac pain. Experimental evidence strongly indicates that the myocardial muscular tissue is insensitive and does not cause pain by ischemia or failure of action through anoxemia or degeneration. Cardiac pain is expressed only through the afferent nerves of the sympathetic portion of the autonomic nervous system. Cardiac pain occurs when functional failure of normal reflexes produces conditions that stimulate the afferent nerve endings in the adventitia of the aorta and coronary vessels. Experimental evidence also strongly indicates that vascular distention rather than vascular spasm is the usual cause of cardiac pain.

Chronic Hyperparathyroidism.—Johnson and Wilder report that the repeated injection of parathyroid extract produced, in puppies and young rats, a uniform skeletal abnormality that is characteristic of osteitis fibrosa osteoplastica (von Recklinghausen). A lacunar resorption of the trabeculae and corticalis of bones resulted, with replacement of marrow and cortex by fibrous connective tissue and osteoid tissue. Giant cells appeared and cysts were formed. The administration of viosterol together with parathyroid extract did not modify significantly the end-results. The results of the experiments confirm the view that the pathogenesis of osteitis fibrosa osteoplastica, as this disease is observed spontaneously in man, is an oversupply of parathyroid hormone and that this disease bears no relation, etiologically, either to osteomalacia or to rickets.

Immune Transfusion in Lobar Pneumonia.—Eight cases of pneumococcus lobar pneumonia, six due to pneumococcus type III and two to pneumococcus type II, were treated by Barach and Soroka by transfusion of from 1,000 to 1,600 cc. of blood from donors immunized over long periods. No favorable effect was observed on the clinical condition of the patient as a result of any of the transfusions. The introduction of a protective substance present in the donor's blood could not be demonstrated in the patient's blood in the five fatal cases and appeared to have no influence on the course of the disease in the three recovered patients.

Leather-Bottle Stomach.—Friedenwald and Morrison believe that the term "leather-bottle stomach," as suggested by Wyard, should be reserved as a general term for a number of conditions which though similar in gross appearance present, however, a varied pathology. Clinically, it is rarely possible to differentiate these types. This condition may present a local or a diffuse involvement. The term "linitis plastica" should be discarded and a more appropriate term, such as "carcinoma plastica," be substituted. The condition is represented by a small-cell epithelioid growth having definite pathologic characteristics, the diagnosis of which cannot be made except following a most painstaking microscopic examination. The clinical as well as the roentgen manifestations of leather-bottle stomach are similar, no matter what the characteristic pathologic changes may represent. These manifestations are largely those of carcinoma, though there appears to be a type that is definitely not malignant. The carcinoma plastica and fibromatosis forms produce death by inducing profound anemia and malnutrition; the scirrhous carcinomatous type, largely as the result of metastases. The treatment is surgical; the only hope for a complete cure lies in radical surgery in the form either of pylorectomy or of gastrectomy. Occasionally, palliative measures such as gastro-enterostomy may afford relief.

Oral Administration of Corticosuprarenal Extract.—Britton and his associates demonstrate the effectiveness of corticosuprarenal extract given by mouth. It prolongs considerably and possibly indefinitely the lives of suprarenalectomized cats and brings about complete recovery from even the severest symptoms of suprarenal insufficiency, when given by the oral route. The low blood sugar values found in suprarenalectomized animals are markedly increased, and the high nonprotein nitrogen values and blood cell volumes are reduced toward or to the normal levels, during the recovery period. Animals that have refused food may be induced to eat within an hour after administration of the extract. These observations are in keeping with those produced by intraperitoneal injection of the material. Large amounts of the extract, approximately three to five times the intraperitoneal dosage, were necessary by mouth in order to produce comparable results. Epinephrine given by mouth in similar concentration to that found in corticosuprarenal extract, and also dextrose solutions, have no noteworthy effect on suprarenal insufficiency.

Effect of Exercise on Colonic Motility.—The effects of short periods of strenuous treadmill running on the motility of the colon of dogs completely recovered from appropriate surgical intervention were recorded by DeYoung and his associates by the balloon method in a series of nine dogs. It was found that during an exercise period there is in a majority of cases a marked rise in colonic tone and motility. The rise is not coextensive with the running period. It begins usually from one to three minutes after the start of exercise and recedes after a few minutes without reference to the duration of exercise. From studies following a variety of denervation procedures it is concluded that the appearance of the rise depends on the intactness of at least one of two parasympathetic inflows, probably vagal, entering the colon over the ileocecal juncture from above. The rise did not appear in a dog that ran with evident fear of the treadmill until after he had been conditioned to run without this emotion. Following the exercise period there is usually a period of subnormal activity of varying length—sometimes as long as forty-five minutes.

Physiology of Secretin.—According to Still and his associates, the cholagogue action of secretin is not due to metabolites arising from the pancreas or other abdominal viscera. Secretin, alone, stimulates the hepatic cells, resulting in an augmentation in the flow of bile, which in acute and chronic experiments of from eight to ten hours in length contain lower concentrations of the bile salts. Secretin does not cause circulatory changes in the liver as measured by the liver volume method.

Vomiting Reflex from Distended Pyloric Pouch.—Goldberg describes experiments in which he noted that reflex vomiting can be induced by distending an isolated pyloric pouch until the pressure within the pouch rises above a certain constant level which can be definitely measured. The afferent side of this reflex arc is entirely through the vagus nerves. Supposedly denervated pouches contain enough intact vagus fibers to carry these afferent impulses.

Mineral Content of Pigeons Fed Polished Rice.—McHargue and Roy state that, in polishing brown rice, substances containing considerable quantities of ash, manganese, iron, calcium, magnesium, phosphorus and potassium are removed in the offal. When pigeons are fed polished rice until polyneuritis develops, analyses of the ash of their carcasses show marked diminution in magnesium, phosphorus and potassium content as well as in the content of some of the minor constituents. Unpolished rice, wheat and yellow corn cured polyneuritis and restored normal body weight, showing that they contained vitamin B_1 and B_3 factors, though yellow corn produced slower recovery and gain in body weight than unpolished rice and wheat. Barley, rye and white corn contained vitamin B_1 but were deficient in the vitamin B_3 factor. Wheat, unpolished rice and yellow corn contained more of the elements copper, manganese and iron than barley, rye and white corn, which leads the authors to infer that the minor mineral constituents as well as the major constituents calcium, magnesium, phosphorus and potassium are factors in protecting pigeons from polyneuritis.

Function of Sphincter of Oddi.—Lueth is convinced that the intramural portion of the common bile duct possesses a special sphincteric mechanism, that a sphincter of the papilla exists and that this sphincteric mechanism is intimately coordinated with duodenal peristalsis and tone but may function independently of the duodenum. His data do not permit him to conclude whether the portion of the sphincteric mechanism located in the duodenal musculature has a reciprocal relation with the sphincter of the papilla or whether it functions independently of the duodenal musculature.

Menstruation Following Ovariectomy in Monkey.—In Pithecus (Macacus) rhesus, van Wagenen and Aberle found that excision of both ovaries early in the cycle (from seventy-two hours to the tenth day and in one instance on the thirteenth day) was followed by menstruation after an interval of five or six days. In amount and duration the saguineous discharge was not distinguishable from the normal menses of the individual animal. Microscopic examination of the ovaries showed that bleeding could occur in the absence of a mature follicle or young corpus luteum. Menstruation from an endometrium of interval type occurred in animals operated on on the fourth and fifth days of the cycle. Removal of a single ovary on the fourth day of the cycle was followed in one case by menstruation on the fourth day following the operation, but in another animal no postoperative menstruation occurred. Both bilateral and unilateral ovariectomy failed to induce bleeding when performed on the first day of menstruation.

Injections of Sympathetic Nerves.—Flothow states that the most satisfactory diagnostic procedure for conditions affected by the sympathetic nervous system is the direct injection of the sympathetic nerves with procaine hydrochloride. By means of these diagnostic injections it is possible to determine accurately whether or not therapeutic measures should be directed toward the sympathetic nervous system. The two factors most frequently involved are pain and diminished blood supply. Diagnostic injection gives definite information as to the relief of pain and as to the quantitative increase in vascularity that may be obtained by therapeutic measures. Alcohol injection of the sympathetic nerves is an established therapeutic measure. The author has used it successfully in arteriosclerotic conditions, Buerger's disease, Raynaud's disease, chronic polyarthritis, trifacial neuralgia, atypical facial pains, angina pectoris, trophic ulcers, neurotrophic skin lesions, diabetic neuritis, and other conditions. Tables are presented including sixty-four diagnostic injections, forty-eight of which were followed by alcohol injection with uniformly good results. Alcohol injection may be used as a substitute for surgical removal of sympathetic ganglions when the latter is not indicated. Alcohol injection does not have the permanence of the operation and is therefore not indicated when permanent maximum blood supply is essential, except when operation is definitely contraindicated. Alcohol injection can be used more successfully than the LeRiche operation in all the conditions for which this operation has been advocated. Surgery or alcohol injection on the sympathetic nervous system should be preceded by diagnostic procaine injection. This diagnostic injection has taken sympathetic therapeutic measures entirely out of the realm of guesswork.

Diagnostic Pneumothorax.—Faulkner believes that diagnostic pneumothorax has a wide application in thoracic surgery. It is easy to perform and in properly selected cases is rarely followed by complications. The use of this procedure permits early selection of cases that probably will require surgery and allows one to recognize those that are likely to show recovery by conservative measures. The employment of pneumothorax along with bronchoscopy and iodized oil has increased the author's percentage of cures and has avoided operation in a number of cases.

Bronchoscopic Treatment of Bronchiectasis and Lung Abscess.—Clerf is of the opinion that in pulmonary abscess, bronchoscopy should be considered a part of the conservative plan of treatment if there is evidence of interference with drainage. Every case of unilateral bronchiectasis should have the advantage of diagnostic bronchoscopy to rule out possible endobronchial lesions. This is particularly important if surgical treatment is contemplated. In bilateral bronchiectasis occurring in adults, bronchoscopy is an aid to the internist and its benefits are temporary; in children, bronchoscopy combined with other appropriate measures is often followed by excellent results.

Surgical Treatment of Bronchiectasis and Lung Abscess. — Harrington states that pulmonary suppuration is usually progressive. The surgical treatment should be as conservative as possible and consistent with effectual treatment. The most common operative procedures are artificial pneumothorax, phrenicotomy, surgical collapse and partial pneumonectomy. The type of operation depends on the time in the course of the disease that treatment is instituted, the situation and extent of the lesion, and the general condition of the patient. In most cases multiple operative procedures are required to effect symptomatic cure. The operative procedures and results are given concerning 111 cases. There were 10 deaths (9 per cent). In 64 cases (66 per cent) there was cure or from 50 to 90 per cent relief of symptoms, and in 16 cases (17 per cent) symptoms were not relieved. The pulmonary infection was due to malignant lesions in 5 cases and to actinomycosis in 2 cases, with temporary improvement of symptoms due to relief of sepsis.

Extrapleural Paraffin Filling.—Rogers believes that extrapleural compression has rightfully won a place in the surgical treatment of chest disease. This method broadens, to some extent, the indications for surgical intervention. The results are gratifying when one adheres to the more specific indications. The paraffin mixture is probably the best compression substance available at present. In the future a substance that will have a lasting effect of continuous pressure and that will eventually be absorbed or assimilated by fibrous tissue invasion may be found.

Diabetes and Tuberculosis.—Banyai presents an analysis of thirty-one cases of diabetes mellitus complicated by pulmonary tuberculosis. Tuberculosis complicating diabetes often has an insidious onset and larvad, atypical forms. Unusual, subapical or perihilar localization is frequent; bronchopneumonic lesions dominate the picture. The cause of lack of symptoms and absence of physical signs in early cases may be sought in the nature and localization of the disease, and in the fact that acidosis is liable to mitigate or suppress allergic reactions and that in the aged (40.9 per cent of Joslin's diabetic tuberculous patients were 50 years or older) the symptoms of tuberculosis are often inconspicuous and the physical signs hard to detect because of physiologic changes characteristic of this age period. In the presence of respiratory or constitutional symptoms or signs, or when diabetes is well under control and the patient is still not doing well, the presence or absence of pulmonary tuberculosis must be ascertained by means of stereoscopic roentgenograms. When the pulmonary disease reaches advanced stages, symptoms become more manifest and physical signs more easily detectable. The author has never seen insulin cause any focal or constitutional reaction. The indications and contraindications for surgical intervention are the same as in nondiabetic patients.

Tuberculosis and Diabetes.—Gotten considers pulmonary tuberculosis complicating diabetes a serious condition, carrying a mortality rate of over 50 per cent in the first year after onset. These patients apparently have a lower state of resistance than the nondiabetic patients. However, with a most careful course of treatment, embracing the use of insulin and a proper adjustment of diet for maintaining adequate nutrition, many can be restored to health.

Treatment of Morphine Addiction. — Rubenstein states that in tuberculosis one is not infrequently confronted with the problem of treating narcotic addiction. By reason of their proneness to aggravate the chest condition, the usual withdrawal methods have proved far from satisfactory in their application to the tuberculous patient. The author has successfully applied Pavlov's conditioning method at the Los Angeles Sanatorium to two persons with pulmonary tuberculosis who were addicted to the morphine habit. In both cases it was found that the treatment was rapid and effective and did *not* produce the so-called withdrawal symptoms.

Effect of Environment on Normal and Tuberculous Guinea-Pigs.—Greenfield points out that normal guinea-pigs live longer in an open building than they do in either a wooden or a glass building. Offspring of normal guinea-pigs housed in an open, a wooden or a glass building are able to live and produce young. Guinea-pigs are more able to combat a tuberculous infection when they are housed in an open building than they are when housed in either a wooden or a glass building. The percentage of days of life lost because of tuberculous infection in an open building is 11.6, in a wooden building 32, and in a glass building 24.1. Offspring of tuberculous guinea-pigs housed in an open building are able to live and produce young, while offspring of tuberculous guinea-pigs housed in either a wooden or a glass building live only a short time.

Interpretation of Pathology of Pulmonary Tuberculosis.—According to Medlar and Sasano, massive pulmonary tuberculosis in the rabbit is dependent on the rupture of pulmonary tuberculous abscesses into the bronchial tree and inhalation of the contents of these abscesses into the previously uninvolved lung tissue. It seems plausible that this is also the method of extensive dissemination of tuberculosis within the human lung. The pathology of pulmonary tuberculosis is essentially a process of inflammation and repair. Interpreted on the basis of inflammation and repair, the complex pathology becomes greatly simplified and more easily understood. The authors believe that the complex terminology used to describe the bizarre pathology of pulmonary tuberculosis is unnecessary and confusing. The term "specific" when used in connection with tuberculous lesions should be restricted to denote a biochemical, not a morphologic, specificity.

Bacterial Synergism in Disease Processes.—In connection with two cases of progressive gangrene of the abdominal wall, Meleney emphasizes the fact that both occurred following the drainage of a peritoneal abscess, presumably of appendical origin. In both, the streptococcus was present in the first cultures. In both cases the peritoneal infection took care of itself. In both, the gangrene developed in the region of silkworm-catgut retention sutures. Both patients complained bitterly of the pain associated with the lesion. In both, conservative treatment failed to check the progress of the disease. Both recovered promptly after the wide excision of the lesion. In both instances the micro-aerophilic streptococcus (anaerobic by preference) was found in pure culture far out in relatively normal tissues and in the red zone beyond the gangrene. In both cases the gangrenous tissue contained both the streptococcus and the staphylococcus. Practically identical results were obtained when the organisms from these two cases were injected into experimental animals. The fact that these organisms have an adjuvant action on one another seems to be confirmed by the animal experiments. The nature of this phenomenon has not been clearly shown and will have to await further experimentation. The results of the author's study so far seem to indicate that one organism does not initiate a process which the other completes at a later time, as is the case with a combination of proteolytic and saccharolytic organisms. The study indicates rather that it is necessary for them to be growing together intimately and that the product which is the cause of the gangrene is made by the action of one organism on some intermediate product of metabolism produced by the other, as is the case with certain combinations of fermentative bacteria.

Spina Bifida.—Coughlin is of the opinion that, by rigidly following a technic which he outlines, the operative mortality in spina bifida should be 0. An open sac alone is not a contraindication to operation. The diagnosis of myelocele does not always contraindicate operation. The diagnosis may be wrong when the defect is in the lumbosacral region. A total paralysis of the sphincters, in the presence of a myelocele, is a distinct contraindication to operation. In meningomyelocele the only way to be certain with regard to the presence of the cord in the sac is to open and look within it. Infants aged less than 4 days stand the operation best. The author believes that there is no need to make any kind of osteoplastic reconstruction of the spinal canal. Paralyses in certain cases of meningomyelocele are improved by operation.

Section of Posterior Root of Trigeminal Nerve.—Van Wagenen reports five cases in which section of the posterior root of the trigeminal nerve was of necessity done for the relief of pain. In one of these cases the operation was combined with a unilateral upper cervical dorsal rhizotomy. The impression is gained from these and other cases that, while the operation is considerably more hazardous and difficult than that through the temporal route, it is a valuable adjunct to the neurosurgical armamentarium. No evidence was gained from this series of cases that the type or area of anesthesia differs from that which occurs when the trigeminal root is sectioned by way of the temporal fossa, provided the root is totally divided. In two instances in which only the lower half of the nerve was sectioned there was a preservation of sensation over the face in all but several localized areas.

Sigmoid Megacolon Volvulus.—Weeks points out that there is a definite clinical entity known as volvulus of a megacolon of the sigmoid. In the majority of cases the dilatation in this condition is limited to the sigmoid. This condition, unlike uncomplicated Hirschsprung's disease, occurs in middle age. To prevent further recurrence, the involved loop should be resected, preferably by the Mickulicz procedure.

Interparietal Hernias.—According to Lower and Hicken, interparietal hernia is a term used to designate a group of hernias that occur in the inguinal region between the various layers of the abdominal muscles and are classified according to the anatomic location of the hernial sac. Properitoneal hernia includes all those cases in which the hernial sac lies between the peritoneum and the transversalis fascia; 119 such cases have been reported. In interstitial hernia the sac lies between the transversalis fascia and muscle, between the transversalis and internal oblique muscles, or between the two oblique muscles; 348 such hernias have been reported. In superficial hernia the sac lies between the skin and the aponeurosis of the external oblique muscle. The authors have found reports of 123 cases of this type in the literature. In interparietal hernia the sac may be monolocular or multilocular, the latter being the form present in the majority of cases. The usual clinical picture is that of intestinal obstruction. Treatment consists of early recognition and immediate relief by operation.

Digital Gangrene Following Nerve Block.—Garlock describes four cases of gangrene of the finger following digital nerve block anesthesia. After careful consideration of all the available facts, he states that the cause for this complication is undoubtedly a local one. The essential factor is a thrombosis of the digital vessels produced by the tight application of a narrow tourniquet which causes local tissue injury and marked slowing of the blood stream. An added factor may be the mechanical presence of the anesthetic agent distal to the point of constriction of the tourniquet. The prevention of complications of a similar nature rests with the care with which a tourniquet is applied about the base of a finger. A tourniquet of a narrow caliber should be avoided, and for ordinary purposes occlusion of the arterial supply is contraindicated. When a bloodless field is desired, a properly applied Esmarch bandage is more effective and safer.

Cutaneous Sensory Fibers.—According to Ranson, there are good reasons for believing that pain is mediated by sensory fibers of the smallest diameter. In the spinal nerves of the cat the majority of these are unmyelinated. In the trigeminal nerve of the cat and in the spinal nerves of man a larger proportion of these fine fibers may have acquired myelin sheaths. It is the fine, nonbifurcating fibers of the trigeminal nerve that carry the sensation of pain from the skin of the face; these descend in the spinal tract of the trigeminal nerve, which is continuous below with the tract of Lissauer. These two tracts and the long column of gelatinous gray matter associated with them receive the pain fibers from the skin.

Ectodermoses in Epilepsy.—Yakovlev and Guthrie discuss three types of congenital neurocutaneous syndromes (Recklinghausen's neurofibromatosis, Bourneville's tuberous sclerosis and angiomatosis of the brain with trigeminal nevi) and present a series of fourteen case records illustrating the association of these syndromes with mental defect and epilepsy. All three syndromes exhibit remarkable parallelism in their clinical and pathologic manifestations. All three conditions are the result of congenital maldevelopment bearing electively on the organs of ectodermal derivation: nervous system, eyeball, retina and skin. The ectodermal origin of developmental anomalies in these conditions is evident from the tendency of congenital lesions to a metameric distribution in the skin and in the nervous system. However, in the case of vascular nevi the distribution of nevi seems to correspond with areas of sympathetic innervation rather than with true metameres, suggesting thus that this congenital vascular anomaly may have its origin in some developmental defect of vasomotor innervation. The relationship of these lesions to the process of folding and of differentiation of embryonal sheets and to the primitive neural tubes is suggested by topographic predilection of the clinical and pathologic manifestations of the three neurocutaneous syndromes to the cephalic and caudal ends of the body. The malformations may bear more or less exclusively on the neuro-ectodermal tissues, as is the case in tuberous sclerosis and in the so-called central Recklinghausen's disease, or may be confined to the mesodermal element such as blood vessels, as is the case in angiomatosis of the brain. However, the mesodermal hyperplasia (connective tissue, fibroblasts and blood vessels) is present in the characteristic lesions of all three congenital conditions, developing either as a parallel associated malformation or as a secondary reaction. All three congenital syndromes have their common origin in a malformation of the ectoblast. Both clinically and pathologically, they all may be included in one group under the term of congenital ectodermoses. The three neurocutaneous syndromes arising on a common ground of congenital ectodermal malformation are not identical. They probably differ in the period of embryogenesis at which the disturbance occurs; they differ also in the predominance of one or other of the ectodermal structures involved and, therefore, in their clinical and pathologic manifestations; they differ also in the degree of participation of mesodermal elements; thus, the mesodermal element is most prominent in the vascular neurocutaneous syndrome, with regard to which the term congenital ectodermosis of vascular type (*ectodermosis telangiectodes*) seems to be justified.

Liver in Degeneration of Cord.—Seventeen cases of pernicious anemia complicated by subacute combined degeneration were studied histopathologically by Davison. Seven of the patients had been subjected to liver therapy. Clinically, there was apparent improvement in the neurologic signs and symptoms in only two of the treated patients. Histopathologically, all the treated patients showed progressive glial changes (gliosis). These changes were not observed in the untreated patients with subacute combined degeneration. The myelin sheaths and axis cylinders were not influenced by the liver therapy.

Myocardial Scars Following Coronary Obstruction.—MacCallum and Taylor present three typical photographs to show the contrast between the effect of obstruction of the anterior descending branch of the left coronary artery, of its left circumflex branch and of the right coronary artery. These are the common types although both arteries may be occluded and obstruction of other and smaller branches doubtless produces characteristic scars when this is not obviated by the collateral circulation. Obstruction of the anterior descending branch of the left coronary artery commonly results in scarring of the more anterior part of the interventricular septum, sometimes even extending through to the right ventricle, and of the apical and more anterior part of the wall of the left ventricle. In sharp contrast with this, the obstruction of the right coronary artery, and especially of the more distal portion which partly encircles the base of the left ventricle and sends branches downward to its wall, produces a scar and dilatation which begins sharply in the midline of the interventricular septum and extends backward behind the papillary muscles of the mitral valve to curve round on the more posterior part of the wall of the left ventricle. Scarring of the wall of the right ventricle seems to be rare and may be due to the more direct course of the branches of this artery which supply it. Obstruction of the left circumflex branch of the left coronary artery results in a scarring and thinning of the wall of the left ventricle in its more median portion, between the province of the left anterior descending branch and that of the right coronary. The interventricular septum is not approached. Thrombi formed in these sacculations may give rise to emboli which can pass into the branches of the aorta. If the scarring of the interventricular septum is such as to extend through to the endocardium of the right ventricle, thrombi formed there may give rise to emboli which would pass into the lung.

Peritonitis of Appendical Origin.—Foss calls attention to the fact that acute appendical peritonitis is causing more deaths in this country in individuals under 40 than is cancer, accounting for over 20,000 deaths each year, despite improved operative and postoperative technic and widespread propaganda for early diagnosis and treatment. About 50 per cent of the patients with peritonitis are given laxatives before admission to the hospital. The average length of time intervening between the onset of symptoms and surgical consultation is still too great. In the author's series it was four days. Immediate operation as soon as the diagnosis is made, the removal of the appendix, and ample tube drainage accurately placed constitute the essentials of treatment, while maintenance of water balance and the withholding of fluids by mouth are the chief details of postoperative care. Mortality depends largely on factors controllable prior to the patient's admission to the hospital, and of these, earlier diagnosis and omission of purgation are of particular importance. Comparative mortality statistics are of but little significance unless all the factors are considered, the chief of which is duration of time taking place between the onset of symptoms and the operation. The author believes that there is great need of further stressing the incalculable importance of early diagnosis and of making clear the simplicity, in nearly all cases, of making that diagnosis.

Mechanism of Ultraviolet Irradiation in Rheumatic Diseases.—Llewellyn and Jones stress the fact that "rheumatism" is primarily the outcome of an inborn tendency to "instability" of the heat or temperature regulating mechanism. The storage in the skin of the amino-acids tyrosine and cystine is of fundamental and probably etiologic significance. Tyrosine is the mother substance of which the temperature-regulating hormones thyroxine and epinephrine are chemical derivatives and also of melanin through the action of the ferment tyrosinase. Tyrosine enters into the formation of insulin, another heat-producing hormone, and the sulphur content of insulin is derived from cystine. The amino-acids tyrosine and cystine exist in free state in the blood and have been detected in the sweat. The blood content of tyrosine and hence potentially of thyroxine and epinephrine is increased by ultraviolet irradiation.

"Avertin" in Gynecology.—Young believes that, employed in a dosage which does not exceed 0.1 Gm. per kilogram of body weight, "avertin" is a safe drug. In this dosage it may suffice for minor operative work, but a supplementary inhalation anesthesia is usually required. Its advantages are: (1) ease, comfort and certainty of induction; (2) reduction of postoperative discomfort and sickness, and (3) reduction of postoperative pulmonary complications. In the author's series of 1,000 unselected cases there were no deleterious effects, either immediate or remote. There were five deaths in the series, and in no instance could the fatal issue be attributed to the "avertin."

Treatment of Pernicious Anemia by Injections of Liver Extract.—Harrington and Fleming report the results they obtained with the intravenous and intramuscular administration of a liver extract in four cases of pernicious anemia. This form of treatment produces a rapid and effective reticulocytosis in from three to four days. In one case it caused a sharp reaction, which, however, was in no way alarming. The authors believe that the intravenous administration of liver extract should be reserved for severe cases and may obviate blood transfusion. Ordinarily the extract should be given intramuscularly. The injections should be discontinued as soon as effective reticulocytosis has occurred, and treatment continued orally.

Hepatic Efficiency.—Rolleston believes that it is in acute rather than in chronic lesions of the liver that functional tests are likely to give constant evidence of impaired activity. In acute yellow atrophy, in which all or nearly all the parenchyma of the liver and presumably its functions are involved, the clinical picture usually gives sufficient data for the diagnosis, and the need for further tests may not be obvious. In the treatment of syphilis by arsphenamine preparations, evidence of impaired function in the excretion of bile—the presence of bile acids in the urine by Hay's test, and so-called latent jaundice by van den Bergh's test—is valuable by giving a warning that changes are taking place in the liver and so indicating cessation of the injections and the administration of dextrose, in order to avoid the more severe accidents of postarsphenamine jaundice. The methods have the advantage of simplicity and rapidity over the levulose test in routine work. In chronic ascites due to causes other than hepatic disease, such as tuberculous peritonitis and carcinomatosis of the peritoneum, negative results with functional tests, such as rose bengal, may be of use in diagnosis. The value of van den Bergh's test in connection with different forms of jaundice may be regarded as established. It is in ordinary portal cirrhosis that, in spite of many reports to the contrary, functional tests so often fail, especially when their help is most needed. The levulose and galactose tests have been much employed, but the compensatory power of the liver may vitiate the results, especially in latent cases. Urobilinuria, common in cases of structural change and functional disorders of the liver, provided bile enters the intestine, is not pathognomonic of any one disease of the liver and may occur when blood destruction is taking place in any part of the body.

Vitamin D Deficiency, Dental Caries and Tonsillar Enlargement.—The investigation of Mackay and Rose was confined to the effect, if any, on the teeth and tonsils of school children of vitamin D deficiency in infancy or early childhood. Forty-six children aged from 6 to 10 years, who were known to have had rickets in infancy or early childhood, were compared with forty control children of similar age. The authors have no knowledge that the diet of the two groups of children differed materially when early childhood was passed. Hence they do not claim that their control group consisted of children who had always had sufficient vitamin D, but only that in early childhood the available vitamin D for members of this group was much greater than for members of the rachitic group. Moreover, this difference was sufficiently marked to leave an effect at school age on the height, weight and bones of children of the rachitic group. These averaged 2½ inches shorter and more than half a pound lighter than the controls; moreover, one in four still showed deformities of the long bones, and one in five well marked chest deformities. The proportion of children with crowding of the permanent teeth was nearly the same in the two groups, but as most of them had only cut a small proportion of their permanent teeth, not much stress can be laid on this. Hypoplasia of the permanent teeth was almost confined to the rachitic group, 22 per cent of whom showed hypoplasia, which in 15 per cent was fairly severe. Since only one control case presented hypoplasia, and that slight, these results in children fall into line with the evidence that D deficiency in young animals produces defective dental structure. In spite of the very different incidence in the two groups of hypoplasia of the permanent teeth, the amount of caries of the permanent teeth appeared only slightly greater in the rachitic group than among the controls, and the difference is such that it cannot be held to indicate that vitamin D deficiency in early childhood is an important factor in determining the development of caries. The amount of caries of the temporary teeth was about the same in the rachitic and the control groups. Nor does D deficiency in early childhood appear to have influenced materially the tendency to the development of enlarged tonsils or of enlarged cervical lymph nodes. The two groups were roughly similar in these respects, both showing the usual high incidence of tonsillar enlargement and cervical adenitis seen in children attending a hospital outpatient department. The authors suggest that the very similar incidence of dental caries shown in those children who had had rickets and in the controls strongly suggests, if it does not prove, that vitamin D deficiency in infancy and early childhood, with consequent hypoplasia of the permanent teeth, is not the main factor in determining the incidence of dental caries. Such a deficiency may be one among a variety of etiologic factors, but if it were the predominant causative factor, the incidence of caries in the rachitic group should have been far greater than among the controls.

Blood Platelets After Splenectomy.—Galloway reports that removal of the spleen in three cases of thrombocytopenia led to an immediate and great increase in the number of circulating blood platelets. In the recorded cases they reached their maximum on the eleventh day. Subsequently they diminished in number but still remained much above the preoperative level even after twelve months and twenty-one months. More platelets reach the spleen in the splenic artery than leave it in the splenic vein. There is a great accumulation of platelets in the blood in the substance of the spleen. The observations suggest that the spleen is an important site for platelet destruction.

Achlorhydric Dyspepsia.—Andrew states that there are many cases of dyspepsia, often overlooked, in which the test meal reveals diminution or absence of free hydrochloric acid in the gastric juice. The therapeutic test of administration of acid is of value in those cases which do not give an early and maintained response to alkali treatment when organic and reflex causes for the dyspepsia have been excluded. A confirmatory test meal, at least by the qualitative method, is useful as a guide to treatment. It is important to recognize the relation of achlorhydria to the preanemic state and the early spinal cord changes of addisonian anemia.

Endocrine Therapy.—Vincent summarizes the scope and limitations of endocrine therapy thus: The cases in which it is possible to employ a true endocrine therapy—artificially to take the place of the internal secretion of a gland—are those of the thyroid, parathyroid, pancreas (insulin) ovary, suprarenal cortex, suprarenal medulla, and the two parts of the pituitary. Of these, only one, the thyroid, is known to produce any effects when given by the mouth. The others must be administered by some other route. Epinephrine and preparations of posterior pituitary are chiefly used as drugs apart altogether from the question of internal secretion and substitution therapy. The anterior lobe of the pituitary, though it produces marked effects on growth when injected into animals, has not yet been demonstrated to be of service in the treatment of disease in the human subject.

Bronchoscopic Diagnosis of Bronchopulmonary Cancer.—Soulas asserts that in spite of the important acquisitions in roentgen diagnosis and classification of pulmonary cancer, recent publications still demonstrate the difficulty in such diagnosis. The diagnosis is rarely determined at the beginning but generally at the time when aggravation of symptoms or metastases have appeared. He reviews two instances in which bronchoscopy confirmed the clinical examination by reason of the endoscopic information and the biopsy; in four other instances the diagnosis was very difficult, but bronchoscopy without biopsy enabled him to make an exact diagnosis on the basis of the endoscopic signs alone. In four other instances endobronchial examination did not indicate the existence of a bronchopulmonary cancer but, on the contrary, signs of syphilitic stenosis, compression without bronchial participation, and suppuration. The author believes that bronchoscopy should not replace roentgen and clinical examinations but should follow and complete them. However, its function is primarily to confirm or establish an early diagnosis of bronchopulmonary cancer. Bronchoscopic diagnosis depends on a number of characteristic signs. It is not necessary to insist on well known clinical signs in budding, vegetating cauliflower-like bronchial tumors when it is easy to obtain histologic confirmation by biopsy. The endobronchial picture peculiar to cancer is characterized by deep red coloration, more or less stenosing infiltration of the mucosa, a shagreen aspect, an unusually hemorrhagic condition, anomalies in direction and form of the bronchi, stenosis of the orifices, stenosis of an endoparietal origin not due to compression, and especially the diminution or still more the abolition of the physiologic movements of the bronchi, which may progress to the point where the bronchus moves as a whole. This absence of expiratory contraction and inspiratory expansion and this abolition of peristaltic movements of the air passages are pathognomonic.

32: 297-392 (Oct.) 1931

- *Diagnosis of Cystic Degeneration of Kidneys. J. A. Ratner and I. L. Zimhes.—p. 297.
- *Formation of Calculi in Gonorrheal Pyelitis, with Case Report. I. Mihalovici.—p. 305.
- Histopathologic Study of Neck of Bladder. M. Jungano.—p. 314.

Diagnosis of Cystic Degeneration of Kidneys.—Ratner and Zimhes state that cystic degeneration of the kidneys is a congenital defect difficult to diagnose because of its lack of specific symptoms, the evidence of a granular tumor in the lumbar region being the only objective symptom. One of the most frequent signs is polyuria, followed by oliguria as the condition gets worse and ending with anuria. The urine is of very low specific gravity and contains albumin. Early diagnosis is extremely rare, and the decisive points of the diagnosis are the finding of a unilateral or a bilateral tumor in the lumbar region and evidence of chronic nephritis. For several years the authors have made special roentgenographic studies of these cases and have found a characteristic general enlargement of the renal pelvis, frequently identical on the two sides. They consider roentgenograms as indispensable for the diagnosis when a patient presents evidence of chronic nephritis with the finding of the characteristic bilateral tumor, scarcely or not at all painful, granular, often mobile on palpation and moving with respiration. In case the tumor is unilateral the differential diagnosis will have to be made between a number of lesions according to whether inflammatory complications accompany the picture or not. In uncomplicated cases it will be necessary to eliminate first the neoplasms, especially when hematuria coexists, then the solitary cysts of the kidneys, the parasitic cysts, and hydronephrosis. Complicated cases with infections present the picture of acute pyelonephritis and perinephritis in which only an operation will reveal the anomaly, while a low grade infection with unilateral tumor will raise the suspicion of tuberculosis, calculus, and so on. In this case a bilateral roentgenogram will help to establish the diagnosis. The authors warn of the dangers in taking the roentgenograms, do not attach much importance to the method of introducing air in the perirenal tissues as a diagnostic aid, and mention the studies they are making on the injection of colored solutions in the veins in order to obtain a contrast picture.

Formation of Calculi in Gonorrheal Pyelitis.—Mihalovici states that the formation of calculi due to ascending infections is undoubted nowadays, and he reviews the principal factors for their production in acid urine: (1) the presence of a foreign body to serve as a nucleus for the precipitation of colloids; (2) the loss of crystallization form under the influence of colloids, called spheroidal formation of the crystals, as demonstrated by Keyser of the Mayo Clinic; (3) infection, which effects the same changes in crystals as obtains in number 2, again demonstrated by Keyser, using diluted cultures of Bacillus coli, and (4) retention of urine. The author gives the history of a patient with ascending gonorrheal pyelitis who expelled a calculus formed in the left ureter. Roentgenograms show that this ureter was constricted below the fourth lumbar vertebra and a ureteral catheter was stopped at 16 cm., corroborating the roentgenogram.

- *Phlyctenular Keratoconjunctivitis in Children. P. Woringer.—p. 398.

Meynet Rheumatismal Nodule.—Debré and Uhry assert that nodose rheumatism is rare in France in contradistinction to its incidence in Anglo-Saxon and Germanic countries. The nodules of Meynet are found in the subcutaneous cellular tissue and do not adhere to the skin, which retains a normal aspect. They are often revealed by simple inspection as prominences, but most often the nodules are not visible and are then recognized by palpation as small, round, spherical or oval, sometimes discoid, tumors of variable consistency; they are not usually soft but firm, and give the sensation of dense fibrous or even cartilaginous or bone tissue. Their size varies from that of a small grain to that of a large nut; sometimes they simulate tumors or, on the contrary, pass unnoticed until necropsy. In most cases they are very numerous. Their localization is variable with predilection for the top of the skull, particularly the occipital and parietal part, along the vertebral apophyses and the level of the scapula, and in the joints (knees, elbows, fingers). The authors advise that in examining a patient with Bouillaud's disease or chorea, clinicians should not neglect to pass the hand over the vertebral column and the occipitoparietal and scapular regions, in the search for Meynet's nodules to complete and confirm the diagnosis of the disease. These nodosities, usually free under the skin, may be attached to the tendons or even adhere to the subjacent bone. The development of the nodules may be brief (from three to four days), but generally it requires from three to four weeks. The two forms can coexist or follow each other and altogether the entire development does not exceed three to four months. Certain small periarticular syphilitic tumors in their early development resemble Meynet's nodules; however, their more frequent occurrence in adults and their evolution toward softening help in the differentiation. When the nodules adhere to the bone, one should eliminate the possibility of gumma, syphilitic periostitis or tuberculosis of the bone. The rheumatismal nodules present in the occipital region are hard to distinguish from enlarged lymph nodes, which are so frequent in this region in children. The authors believe that there is no connection between the subcutaneous rheumatismal nodules of Meynet and the cutaneous erythematous and painful nodules of endocarditis lenta. The nodules of Meynet are characteristic of acute articular rheumatism, acute rheumatismal polyarthritis or the disease of Bouillaud either when it accompanies a typical polyarthritic crisis or as it occurs in the course of an abortive form of disease. The appearance of Meynet's nodules has a great importance for prognosis, since it indicates that the child has a grave form of rheumatism with severe cardiac localization. One worker reports that among twenty-seven cases of nodose rheumatism there were twenty-six presenting cardiac lesions, while another reports eight cases with cardiac complications in all. The authors believe that Aschoff's nodule is the specific lesion of Bouillaud's disease; that the histologic formation of Aschoff's nodule represents the primary lesion, primordial to the nodule of Meynet; that Aschoff's nodule is a "rheumatismal follicle" and that the nodule of Meynet is a "rheumatismal nodule." The authors find that their bacteriologic examinations were negative, but pathology designates a singular relationship, hard to define, between endocarditis lenta determined by Streptococcus viridans and the disease of Bouillaud. There is a morbid family, dominated by the disease of Bouillaud, which includes rheumatismal chorea, the disease of Still-Chauffard, certain chronic fibrous rheumatisms of infancy and also, in a measure, endocarditis lenta.

Phlyctenular Keratoconjunctivitis in Children.—Woringer asserts that phlyctenular keratoconjunctivitis is of great interest in pediatrics since it is recognized that it has a relationship to tuberculous infection and is often an indication of latent tuberculosis. This entity has for a long time been considered as one of the essential characters of a scrofulous syndrome running parallel to cervical adenitis and chronic rhinitis. It is less frequently encountered in children's clinics than in the services of ophthalmologists. The author found that 85 per cent of the children with phlyctenular keratoconjunctivitis had a positive cutireaction, which usually indicates scrofula; in 15 per cent a relation to tuberculous infection was not demonstrated. In more than two thirds of the cases of keratoconjunctivitis with a recently positive cutireaction, roentgenography showed developing hilus lesions. In children with hilus lesions the mortality is not higher. Keratoconjunctivitis seems to have a favorable influence on the development of tuberculous infection. In old patients who have had a phlyctenular keratoconjunctival infection from two to six years previously, roentgenography demonstrates cicatrices and regions of calcification that are opaque to roentgen rays and denote a good recovery of the bacillary lesions.

Presse Médicale, Paris

39: 1573-1588 (Oct. 28) 1931

*Circulatory Anisergy. M. Villaret, L. Justin-Besançon and R. Cachera. —p. 1573.

Circulatory Anisergy.—Villaret and his associates deplore the fact that clinical studies of the circulatory system have been limited mostly to examination of the heart and the arterial tension when the different circulatory sectors present a relative autonomy that allows the regional and simultaneous establishment of very different degrees of arterial as well as venous pressure, to which they apply the name circulatory anisergy. They divide anisergies into arterial, venous and global. In arterial anisergies they measure simultaneously the recurrent arterial pressure of the extremities and the general arterial pressure, the recurrent arterial pressure being obtained by introducing a cannula in the distal end of an artery and thus registering the pressure maintained by the anastomoses. The pressures are interpreted relatively to those of the general pressure. Several tracings are given of disassociated pressures produced by the administration of suitable drugs, such as ergotamine tartrate to obtain intense peripheral vasoconstriction, α-methylacetylcholine to obtain peripheral vasodilatation, epinephrine after exhibition of yohimbine to obtain with perfect symmetry two opposing effects in two distinct regions, and choline derivatives to obtain dilatation of the retinal artery independent of depressive action on the arterial pressure. Consequently, hypertension or hypotension and dilatation of the retinal artery can be easily disassociated. The authors pass lightly over anisergies of the venous system and refer the reader to their recent book on this subject. They mention that in global anisergies there is, under certain conditions, a complete lack of total coordination between the variants of arterial and venous pressures. They conclude by giving examples of various anisergies and by stating that taking the pressure of a large artery is insufficient to afford adequate information on the general condition of the circulation.

Menstrual Function in Exophthalmic Goiter. G. Meldolesi.—p. 620.
Influence of Sleep on Changes in Acid-Base Equilibrium in Kidney Patients. M. Pisa.—p. 638.

Prophylactic Value of Diphtheria Toxoid.—Pontano criticizes the means of control used for antidiphtheria vaccination in man with the Ramon toxoid. The author took up the study of the problem in an experimental manner and controlled the action of the toxoid vaccine in an infection of the guinea-pig obtained by means of a virulent diphtheria bacterium. He found that the toxoid is harmless even in large doses and always exerts an antitoxic vaccinating potency but that in order to obtain in the guinea-pig a truly vaccinating effect it is necessary to resort to enormous doses of toxoid. A single dose of 5 cc., although enormous with respect to the body weight of the animal, may attain a vaccinating effect. The vaccination in the experiment was only antitoxic. The author, who thinks that the greater danger from ordinary diphtheria lies in the seat of the disease (larynx) rather than in the toxemia, concludes that the animal experimentation does not justify the expectation that diphtheria will disappear or explain the disappearance of cases that, owing to the nature of the seat, are grave, but that it does justify the hope that grave toxemias will disappear if the doses of toxoid are notably increased at vaccination.

*Intestinal Tuberculosis. H. G. Mogena.—p. 1157.
Studies on Bronchial Asthma: Observations on Pollen in Air of Madrid. C. Jiménez Diaz, B. Sánchez Cuenca and G. Canto.—p. 1163.

Intestinal Tuberculosis.—Mogena first recapitulates the gastro-intestinal disturbances likely to occur in tuberculous patients but not due to local tuberculous lesions and consequently of a more benign prognosis, such as dyspepsia with ptosis of the stomach and intestine in patients who have lost considerable weight and in women after pregnancy; dyspepsia produced by forced feeding; diarrhea resulting from achylia with its natural train of symptoms, from tuberculous toxemia and from deglutition of sputum. Intestinal tuberculosis is primary in from 5 to 10 per cent of the cases, especially in children, and secondary, as a rule, to pulmonary tuberculosis; infection occurs by deglutition of sputum and through the circulatory and lymphatic routes. Its site of election is the ileocecal region, where it attacks the solitary and the aggregated lymph nodules and surrounding tissue. The initial symptoms consist of slight gastro-intestinal disturbances, nausea, constipation or diarrhea, anorexia, vague pains in the abdomen and so on. The later constant symptom is diarrhea, up to the point of dehydrating the patient, abdominal pain in the right lower quadrant and borborygmus, all due to increased peristalsis and lack of absorption of ingested liquids. Alternations of constipation and diarrhea have great diagnostic value. Temperature changes are unreliable; loss of weight is rapid in cases in which diarrhea persists. The possible complications are hemorrhage, perforation and cicatricial stenosis. Hemorrhage is rare because the slow development of the ulcerations gives time for obliterating endarteritis or thrombosis to plug up the vessels. Perforation is more frequent and results in a localized peritonitis with adhesions or an abscess, with their individual symptoms. Stenosis may be slight and without perceptible symptoms but in rare cases may lead to intestinal obstruction. Tuberculoma may be present, especially in patients aged from 20 to 40 years, and although often difficult to diagnose, it will be recognized by its insidious beginning with more continuous painful sensations in the right iliac fossa; alternations of constipation with diarrhea; loss of weight and appetite; nocturnal pains, and the presence of a tumor, hard, irregular, painful on palpation, and mobile, which later may produce intestinal obstruction. The lower part of the colon and the rectum may be the seat of a chronic tuberculous hypertrophy, which can be recognized by digital examination and rectoscopy. The possibility of extension of the lesions to the peritoneum and the female genital organs is to be remembered. The diagnosis rests on the study of the symptoms mentioned and the finding of occult blood and soluble albumin. The discovery of the tubercle bacillus has little value in proving localization. Roentgenographic studies are valuable and should be made with the greatest care, the barium meal being followed up every hour from the time it leaves the stomach. The prognosis depends on the time factor and the extension of the lesion, the prognosis of the pulmonary lesion, and the general and social conditions of the patient so far as they will allow him to follow the necessary treatment. Treatment consists of the general treatment for tuberculosis with reliance on administration of vitamin C and D. Surgical treatment by excision or anastomosis is recommended in early cases when the general condition of the patient allows it.

Etiology of Pneumococcal Peritonitis in Children.—Obadalek points out that, whereas the older authorities assume an enterogenic etiology of pneumococcal peritonitis in children, in the French literature a hematogenic infection of the peritoneum is most widely accepted, and more recent studies, which revealed that girls were mostly affected and that they frequently also had a vulvitis, made an ascending infection from the vagina appear possible. However, the disease appeared also in boys, and it was thought that in them it originated in the appendix. The author is of the opinion that peritonitis in children is usually caused by invasion from the intestine. In order to corroborate his theory, he tested in animal experiments the feces of children with peritonitis. He reports the clinical histories of thirteen children with pneumococcal and of two with streptococcal peritonitis. In all of them the feces were examined for the presence of virulent micro-organisms by injection into guinea-pigs. Control tests were made in peritonitis cases caused by perforation of the appendix. Nearly all the guinea-pigs that were injected with the feces of children with pneumococcal peritonitis died, and those injected with the feces of the patients with streptococcal peritonitis died too. Necropsy of the animals revealed a diffuse peritonitis, and the pus yielded the same micro-organisms as the peritoneal exudate of the children. However, the guinea-pigs on which the control tests were made survived the injection of feces. From these observations the author concludes that in children the pneumococcal peritonitis and peritonitis of other bacteriologic origin are due to passage through the wall of the intestine. The clinical aspects of the disease likewise speak for the enterogenic etiology, for diarrhea is nearly always present, and in fulminant cases with early intestinal paralysis there exists in the beginning only tenesmus. The vulvitis is a secondary manifestation; it results from a fecal infection of the external genitalia. Pneumococcal peritonitis originating in the female genitalia is extremely rare.

Peculiarity of Human Milk: Investigations on Diastase.—Schlack and Scharfnagel found that if a small amount of raw human milk is added to a starch paste the latter becomes liquefied within a few minutes. This property of human milk to liquefy starch paste is destroyed by boiling. In testing cow's milk and milk from various other animals the authors found that these do not have the liquefying power; except in the colostrum from cows and in mare's milk it is present in rare instances. This liquefying property of human milk is due to its high diastase content. Milk from animals likewise contains this ferment but in much smaller quantities. The author points out that the liquefaction test is a simple method to differentiate between animal milk and human milk. The high diastase content of human milk is of significance for the nutrition of nurslings for the reason that the diastase content of the saliva is very small during the first weeks of life.

Efficacy of Suggestion in Certain Forms of Hemorrhagic Diathesis and of Hemorrhages. G. Wiele.—p. 2084.

Treatment of Paroxysmal Tachycardia.—Hochrein reports experiences with a prophylactic treatment of uncomplicated paroxysmal tachycardia. In patients in whom the attacks could not be counteracted by the usual therapeutic methods (quinine, quinidine, strophanthin, and the like), it was possible to prevent the attacks by a combination of dietetic measures, psychotherapy and, especially, the administration of atropine. The method of treatment and the reaction of the patients are illustrated in two case reports. During a two year observation the efficacy persisted not only during the administration of atropine but also after it had been discontinued. The action mechanism of atropine on the cardiac function during paroxysmal tachycardia is briefly discussed.

Treatment of Infection of Accidental Wounds.—Clairmont and Meyer state that the infection of accidental wounds is often progressive, may necessitate incision and amputation, or may lead to putrid general infection and even end fatally. The mortality rate of the 2,476 cases of accidental injuries that were treated at the surgical clinic in Zurich during the years from 1920 to 1929 was 1.6 per cent. The most effective means to prevent wound infection is to take proper care of wounds as soon as possible. Superficial scratches, cuts, abrasions and tears should be given the same careful attention as deeper wounds, for the authors noted that pyogenic and putrid general infection and tetanus often resulted from these because of lack of proper care. A 5 per cent alcoholic solution of iodine was found to be most effective in the disinfection of wounds. If wounds require débridement it should be done according to Friedrich's method, with subsequent iodinization. But in spite of careful tending of a wound, infection may develop, and for this reason careful wound control and after-treatment are necessary. Whether an amputation is to be resorted to is largely dependent on the attitude of the individual physician. In gas gangrene the decision can usually be made sooner than in pyogenic general infection, in which the bacteriologic aspect is less alarming. If tetanus develops there is always the possibility of influencing the entire organism. The prophylactic application of tetanus serum and occasionally of gas gangrene serum is necessary especially in clinical institutions. However, a certain selectivity seems justified. It is often possible during the first aid treatment to recognize wounds that are predisposed to tetanus or gas gangrene. The authors think that omission of prophylactic serum injection cannot be considered malpractice.

Clinical Observations During Administration of Spleen to Patients with Pulmonary Tuberculosis. R. Birstein and M. Ikonen.—p. 38.

Open Tuberculosis in Young Teachers a Menace to School Children.—Klein gives a detailed report of several class infections, which could be traced to teachers with open tuberculosis. All school children who had been exposed were subjected to clinical, roentgenologic and some also to serologic examinations. Positive tuberculin reactions were observed in from 72 to 73.5 per cent of the children and active pulmonary processes in from 14.7 to 26.9 per cent; among the latter there were from 5.9 to 15.8 per cent of fresh pulmonary infiltrations. The author stresses the necessity of health examinations for teachers and for the students in pedagogic institutes.

Treatment of Incompletely Descended Testis. R. Göbell.—p. 3155.

Prevention of Recurrence After Hernia Operations.—Bassini's method is, according to Adler, the most widely employed operation in the treatment of inguinal hernia. However, Bassini's original method as well as its modifications are followed by recurrence in from 4 to 5 per cent of the cases. To prevent recurrences the author perfected a new plastic procedure which provides reinforcement for the Bassini sutures. He gives a detailed description of the technic, with illustrations of the various stages, and asserts that he employed it in a considerable number of cases. He considers it advisable, especially in large hernias, in recurrent hernias, in older persons and in patients with inferior connective tissue.

Late Results of Cardiac Suture.—Rufanov reports the clinical history of a man, aged 44. Examination revealed a scar in the region of the heart, through which the cardiac movements could be observed. A scar in the back indicated a previous resection of a rib, and the anamnesis revealed that twenty-eight years before the patient had suffered an injury of the heart, which necessitated cardiac suturing. The author describes this case not only because reports on the late results of cardiac suture are extremely rare but especially because the cardiac function is not impaired and the patient is free from pain, in spite of the fact that the pericardium was drained, which must have resulted in adhesions.

Peridural Segmental Anesthesia.—The aim of the new method of regional anesthesia described by Dogliotti is to utilize the advantages of the subarachnoidal spinal anesthesia and at the same time eliminate its disadvantages. In the course of anatomic studies the author discovered that the epidural space is comparatively wide and can be opened at any level except the occipital. He intended to introduce the anesthetic solution into this space at a level corresponding to the operative field, in order to bring it in contact with the nerve trunks in their course within the vertebral canal, between the dura mater and the intervertebral foramen, and within the intervertebral foramina. He then describes the approach to the epidural space. He points out that the first sudden decrease in resistance to the passage of the needle indicates that the ligamenta flava have been penetrated and that the needle has reached the epidural space. Careful observation of this sign gives the certainty that one has reached the epidural space and has not passed farther. In more than 100 anesthesias which the author induced in this manner, this was found satisfactory. But to be entirely safe it is advisable to employ the fractional injection of the anesthetic. The quantity injected first should not be in excess of the maximal dose that is given in subarachnoidal injection (from 0.08 to 0.1 Gm. of procaine hydrochloride in from 8 to 10 cc. of a physiologic solution). If the first injection is made in the subarachnoid space, an extensive anesthesia sets in from five to six minutes later. However, if, as intended, the injection is made into the epidural space, the anesthesia is only slight after five minutes has elapsed. If one is certain of this, an additional 20 cc. is injected, and after another two or three minutes has passed, another dose of from 20 to 25 cc. is injected. The total amount should be from 50 to 60 cc., which is injected in three portions. During the injection the patient should lie on the side on which the deepest anesthesia is desired. The anesthesia generally develops ten minutes after the second injection. After fifteen minutes it is complete and it lasts from one to two hours. In evaluating the advantages of this method the author stresses the absence of hypotension, of paleness and of vomiting, and the fact that the pulse remains comparatively normal.

Zentralblatt für Gynäkologie, Leipzig

Total Prolapse of Urinary Bladder. A. Mandelstamm.—p. 3592.
Instillation Catheter for Anesthesia of Female Urethra. H. Högler.—p. 3595.

Conservative Therapy of Ureteral Fistulas.—Ottow, after pointing out that the majority of ureteral fistulas result from gynecologic or obstetric interventions, emphasizes the great significance of the differentiation between total and partial defects of the ureteral wall. It should be determined whether the continuity of the tube is entirely interrupted or whether there is only an opening in the wall. This is possible with the aid of cystoscopy. The differential diagnosis is significant especially for the treatment, because in cases in which there is only an opening in the wall one can treat the patients in a conservative manner, namely, by introducing a permanent catheter. Because of its simplicity, the author recommends the wider use of this conservative method. However, if this treatment fails, a surgical intervention is necessary.

Epispadias as Cause of Incontinence.—Seynsche reports the clinical history of a woman with considerable epispadias. He evaluates three surgical methods that could have been employed in this case and then shows why he combined vesicovaginal interposition of the uterus with direct muscular plastic operation. He shows that only the combination of the two methods produces conditions that correspond to the anatomic requirements of a vesical closure. The treatment resulted in complete recovery.

*Angioma Venosum Racemosum of Pia of Spinal Cord. H. K. Lassen.—p. 975.
Subliminal and Autonomous Psychic Activity. I. Ostenfeld.—p. 985.
*Clinical Significance of Diastasuria: I. Normal Values in Persons with Normal Pancreas. J. Foged.—p. 991.

Angioma Venosum Racemosum of Pia of Spinal Cord.—Lassen's patient, aged 71, had had for five years mild but increasing symptoms of a nervous disorder, diagnosed as tabes dorsalis. Symptoms of compression of the spinal cord then appeared, with signs of ascending paralysis, and death soon occurred. Necropsy showed an extreme dilatation and intertwining of the subarachnoid vessels, mainly on the posterior side of the spinal cord, from intumescentia lumbalis into the thoracic region and, less intensively, to the lowest cervical vertebra. Histologically the changes seemed to consist of a hypertrophic thickening of the walls of the vessels resembling the primary stages in the formation of varices elsewhere. Corresponding to the extent of the extramedullary changes there were in the spinal cord extraordinarily marked degenerative processes in the nerve tracts in the white matter together with pathologic increase of the blood vessels in both the gray and the white matter. While tabes dorsalis could not be excluded, the main diagnosis was angioma venosum racemosum of the pia of the spinal cord. No syphilitic stigmas were found in the organs. The author states that there are in the literature thirty cases of venous dilatation causing symptoms of compression. With suspected angioma, operative treatment is advised. In nine of the twenty-one patients operated on, improvement or disappearance of symptoms followed.

Clinical Significance of Diastasuria.—On the basis of about 3,700 determinations of the urinary diastase in 287 patients with a normal pancreas and 841 with probably a normal pancreas, Foged states that the normal value of the diastase concentration may be as high as 200 and that in patients with acute or chronic abdominal disturbances a diastase determination of up to 300 cannot be regarded as a certain symptom of pancreas disorder.

74: 1003-1018 (Oct. 15) 1931

*Spondylolisthesis. J. M. Wollesen.—p. 1003.
Acetylcholine: Use in Arteriosclerotic Pain and Gangrene. E. Bloch.—p. 1014.

Spondylolisthesis.—Wollesen says that spondylolisthesis originates on the basis of a congenital defect in the vertebra accelerated by static conditions or by trauma. The insidious cases, which develop slowly during the course of months and years, especially call for the attention of the physician. The sensation of exhaustion in the lumbar region demands thorough consideration of the differential diagnostic possibilities, and if the pain resists medical treatment the diagnosis of rheumatism or neurasthenia cannot be accepted. Roentgen examination gives scanty information on the earlier stages of spondylolisthesis unless there is a prespondylolisthesis, but is of indispensable value in excluding other disorders. Treatment is operative, Albee's method for tuberculous spondylitis being used. The spinous process is split and a portion of the tibia introduced; the result resembles that accomplished by nature in fracture of the column with normally developed bones, when a bony connection is made by means of callus. In his case examination eight months after the operative treatment showed absence of aggravation of the spondylolisthesis, and the patient was wholly without subjective symptoms.

Nordisk Medicinsk Tidskrift, Uppsala

3: 737-752 (Nov. 21) 1931

*Present Status of Chemical Prophylaxis of Syphilis. P. Lépine.—p. 738.
*Pulmonary Tuberculosis and Diabetes Mellitus. E. Møller.—p. 742.
Third Northern Congress on Physiology. A. V. Sahlstedt.—p. 748.

Chemical Prophylaxis of Syphilis.—Lépine calls attention to the fact that the three most powerful antisyphilitic agents available play a part in prophylaxis apparently proportional to their curative ability, and in it each may be said to have its specialty: mercury for local prophylaxis, arsenic for general and rapidly effective protection, and bismuth for the maintenance of a deep immunity.

Pulmonary Tuberculosis and Diabetes Mellitus.—Møller reports the case of a patient, aged 52, with slight adiposity, diabetes mellitus, fibrocavernous tuberculosis of the right lung, tuberculous laryngitis, slight arterial hypertension, arteriosclerosis and slight myocardiac degeneration, the most important diagnosis being the tuberculosis and the next in importance the diabetes. He calls attention to the unfavorable effect of diabetes on pulmonary tuberculosis and to the particularly insidious onset of the tuberculosis in cases with diabetes; occasional stethoscopic examination of patients with diabetes is recommended. The origin of the tuberculous infection in this case is unknown, but a familial disposition is probable and the diabetes is thought to have played a part. A familial disposition to diabetes is also likely. In treatment of the tuberculosis, strict observance of the diabetic diet is urged, with general hygienic treatment.

Ugeskrift for Læger, Copenhagen

93: 1121-1148 (Nov. 12) 1931

*Aneurysm of Aorta. H. C. Gram.—p. 1121.
Considerations on Modern Therapy of Syphilis: III. (Seroreactions). O. Haslund.—p. 1125.

Aneurysm of Aorta.—The case discussed by Gram is that of a seaman, aged 60, with syphilitic infection dating back forty years. The main diagnosis is aortic aneurysm, with syphilis, arteriosclerosis, aortic insufficiency, myocardial degeneration, extrasystole, pulmonary hypostasis, albuminuria, and paralysis of the left recurrent nerve. The author warns that in syphilitic aortitis early diagnosis means everything.

93: 1149-1170 (Nov. 19) 1931

*Hypertension and Complications. C. Holten.—p. 1149.
*Case of Slow Lead Poisoning with Peculiar Etiology. K. Winge.—p. 1154.
Epidemic Myositis. E. Sylvest.—p. 1155.

Hypertension and Complications.—Holten presents a case of primary, so-called essential hypertension in a woman, aged 51, as a good example of the complication of secondary disorders of the heart, brain and kidneys seen in hypertension. The second aortic tone is accentuated, the heart is enlarged and there is grave degeneration of the myocardium. The apoplectiform attack with slight paralysis of the right arm and right facial nerve three months before the start of treatment is ascribed to a cortical or subcortical brain lesion with thrombosis as the probable cause. The only established sign of renal disorder was a slight albuminuria when treatment began.

Case of Lead Poisoning.—In Winge's patient with history of gallstone colic five years earlier and anemia, bradycardia and nervous disturbance since then, there had for the last half year been marked exhaustion with pain in the epigastrium, finally followed by pronounced pain in the epigastrium and nausea. The patient was found to have been employed for seventeen years as scorekeeper in a poorly ventilated rifle shooting gallery; the lead bullets, striking against the iron plate behind the target, where he stood, raised considerable lead dust. Examination of the gingiva and of the blood established the diagnosis of chronic lead poisoning. The earlier symptoms are thought to have been the first signs of the disorder.

ETIOLOGY OF HEART DISEASE *

ROBERT H. HALSEY, M.D.
NEW YORK

While the knowledge of cardiac mechanics was insinuating itself into common medical practice there was a great lapse of time which today one cannot realize. It has taken many centuries to arrive at our belief that nothing happens without there being some cause for it. It is the influence of the accepted scientific spirit which now pervades our intellectual life. The successful practitioner of medicine must not only believe in the "causality principle," as Professor Bridgman[1] states it, but he must push his inquiry even further; for he must find the cause of the effects about which the patient complains and which the structural changes of the heart typify.

A few moments will suffice to recall some of the relatively important steps in the evolution of the etiologic point of view which has so slowly "crept on apace."

In the foreword of the translation of the Smith surgical papyrus, Breasted[2] says: "In this document, therefore, we have disclosed to us for the first time the human mind peering into the mysteries of the human body, and recognizing conditions and processes there as due to intelligible physical causes."

He finds a description of Imhotep, the earliest known physician, who lived about 3000 B. C. and Iry, a specialist in diseases of the digestive system, who lived about 2500 B. C. and whose tomb is at Gizeh. Iry was aware that the heart was the center and pumping force of a system of distributing vessels and recognized, too, the relation of the pulse to the action of the heart. He had begun to count the pulse some 2,500 years before a description of it appears in Greek literature. Herophilus of Alexandria in 300 B. C. used an Egyptian water-clock to count the pulse and, Breasted writes, "He was the one Greek physician who so nearly approached the discovery of the circulation of the blood that there are historians of medicine who believe that he achieved this discovery." But he "does not indicate a recognition of the circulation of the blood."

There is, then, a long interval, 1,928 years, from the time of Herophilus in 300 B. C. up to 1628 A. D., when William Harvey recognized and demonstrated that the blood circulated through the closed system of arteries, capillaries, veins and heart.

Thomas Sydenham (1624-1689) discarded the prevailing theories and philosophies and prided himself on his skill in observation of the patient. He encouraged the physician to practice measures based on the physician's own practical experience and he helped to develop the syndrome idea.

Then Leopold Auenbrugger (1722-1809) developed immediate or direct percussion (1761). In France, Jean Nicolas Corvisart[3] (1755-1821), an inspiring teacher, taught percussion and wrote an important book on the diseases of the heart.

Marie François Xavier Bichat (1771-1802), active as a surgeon and experimental physiologist, placed the science of macroscopic pathology on a firm basis.

René Théophile Hyacinthe Laënnec (1781-1826), in 1819, published his book on auscultation.

After this time there was a scientific method of inspection, palpation, percussion and auscultation by which to obtain the objective information and evidence of structural change with which to make a diagnosis.

In 1858, Rudolf Virchow (1821-1902) showed that the essential changes of diseased tissues were modifications of the normal cells of the body and not an invasion of extraneous cellular organisms, and cellular pathology began.

Pierre Carl Edouard Potain (1825-1901) developed the knowledge of acute and chronic heart disease and its relation to rheumatic fever.

In 1826, Pierre Adolph Piorry (1794-1879) of Poitiers introduced the method of mediate percussion with the pleximeter.

Louis Pasteur (1822-1895) proved the bacterium to be the pathogenic agent in disease.

Ottomar Rosenbach (1851-1907) emphasized the importance of the function of organs and considered the "treatment the same regardless of etiology," but he hoped that the disorder of function would be recognized before lasting anatomic change had occurred.

Moritz Heinrich Romberg (1795-1873) asserted that "We do not consider the mere placing of the disease in this or another column as the ultimate purpose of diagnosis. That is only the necessary premise. The more important thing is to determine to what degree each single patient is injured by his complaint and what cause has produced the momentary disorder."

Ernst Jendrassik (1858-1922), in a contribution to Lewandowsky's work on nervous diseases, said, "Only with difficulty has the etiological point of view gained acceptance in practical medicine. The principle of the etiological specificity of disease implies that every disease entity is produced by a quite particular cause, the different diseases cannot arise from the same cause, nor can different causes produce the same disease."

Knud Faber[4] says: "To the physiologist and the worker in the laboratory, morbid categories are subordinate concepts, but to the physician, to the clinician,

the reverse is the case: he cannot live, cannot speak, cannot act without them. . . . The final aim of medicine is to acquire a knowledge concerning etiology and concerning the consequent development of the morbid process so as to be able to adopt the right line of action."

It has required, therefore, the slow evolution of methods over nearly fifty centuries and the work of many physicians to bring us to the point at which it is possible to follow a definite procedure to inform ourselves sufficiently to devise a method of attack on the cause of some of the diseases of the heart.

It is now within the power of the practitioner of medicine to produce more knowledge and to shorten the time when it will be possible to know definitely the size of the problems of diseases of the heart.

There are three reasons of great importance alike to the patient and to the physician why the etiology of the heart damage should be determined: first, therapeutic; second, prognostic, and, third, prophylactic.

It is important to know whether the murmur heard at the apex arises from a rheumatic infection or from an accidental anatomic thoracic relation. It is perhaps more important to know whether an aortic insufficiency is due to rheumatic infection or to syphilis than to know that it is an aortic disease. It is most important to know whether an attack of congestive failure occurs because of a rheumatic heart, a syphilitic heart, a coronary sclerosis or a hypertensive heart.

Table 1.—*Cardiac Injury as a Factor in the Death of Sixty Per Cent of One Thousand Five Hundred and Forty-Six Patients* [6]

Cardiac Injury	Number of Cases		Per Cent
Congenital		170	18.29
Rheumatic		164	17.65
Carditis	135		
Chronic valvular	29		
Bacterial		67	7.21
Pericarditis	4		
Endocarditis	63		
Syphilis		80	8.61
Arteriosclerosis		448	48.22
Fibrosis	187		
Coronary arteries	191		
Infarct	70		
Total autopsies	1,546	929	99.98

At present the practicing physician considers etiology in what may be characterized as three different languages: the statement of the pathologist, the nomenclature of the International List of the Causes of Death, and the modern clinical diagnoses. These three experiences can and should be written in the same vernacular with increasing accuracy of form and definition. It is not as difficult as it may seem.

These three points of view and the possibility of making them contribute to the knowledge of etiology, as well as to the more accurate estimate of the elements of what is heart disease, seem sufficiently important to merit discussion at this time.

PATHOLOGY

The pathogenic factors that have been active in producing structural changes in the heart can be determined in most cases by the pathologist on gross and microscopic examination. Based on these structural observations, the common etiologic subdivisions may be stated as agents due to bacteria, the organism to be identified and named; congenital defects: rheumatic infection, carditis and valvular disease, the organism not known. Possibly the structural damage is due to a nonspecific reaction to the many strains of streptococci; syphilis; coronary artery disease, cardiac fibrosis and cardiac infarct.

How frequently is structural damage of the heart recognized from necropsy observations? Cabot,[5] in 1926, stated that a cardiovascular lesion is an important factor in 38 per cent of all deaths.

In a series of 1,546 necropsies at the Presbyterian Hospital in New York, Pappenheimer [6] found a cardiac injury to be important in 929, or 60 per cent (table 1).

The heart in the young is damaged by rheumatic infection in aproximately 90 per cent of all instances. Possibly the heart never escapes without some damage from an attack of rheumatism. From autopsy observations made by Pappenheimer, approximately 18 per cent of damaged hearts are so damaged.

Recently Karsner [7] has stated that "at least 20 per cent of patients with rheumatic fever exhibit endocarditis and 60 per cent of endocarditis is of rheumatic origin."

The other bacterial infections are often superimposed on the heart previously damaged by rheumatic infection or occur alone as a new infection but the named bacteria designate the nosologic position. Approximately 8 per cent of necropsies are so designated.

Syphilis, with or without valvular disease, involves the aorta in a few less than 9 per cent of postmortem cases.

The toxins of pathogenic organisms may produce degenerative changes of the parenchyma and secondary interstitial myocarditis.

Probably the most numerous victims of any etiologic group (because occurring in the older age groups) are those with crippled hearts due to the general systemic diseases resulting in arteriosclerosis of the coronary arteries and atheroma of the valves with or without hypertension.

Cabot,[8] states that "simple hypertrophy with or without arteriosclerosis and nephritis is vastly the commonest lesion—it makes 71 per cent of the whole." Rheumatic valvular disease with hypertension amounts to 82 per cent of his series. He states, too, that 77 per cent of heart disease is nonvalvular and that 22 per cent is valvular.

Dr. Pappenheimer's series show fibrosis of the myocardium (187), infarct of the myocardium (70), and coronary artery disease (191) to be 448, or 48.2 per cent of the series. All are diseases resulting from impaired coronary artery circulation.

The chronic diseases of the lungs may produce changes of the right side of the heart which may be severe enough to cause death by hypertrophy, dilatation and failure.

The cardiac conditions associated with thyroid disease are not accompanied by characteristic myocardial changes.

Congenital defective developmental conditions, which are not acquired diseases, may be considered to complete a practical systematic classification from the point of view of etiology.

The pathologic observations are at present the basic standard for the etiologic diagnosis.

VITAL STATISTICS

To understand more clearly how the knowledge of pathogenesis will enhance the value of statistical figures, let us look for a moment at a few tables of the mortality and morbidity of heart disease as now collected. It must be realized at once that the present accuracy of statistics and the diagnosis of heart disease as a cause of death have been relatively recent attainments.

Table 2.—*International List of the Causes of Death in 1919 and in 1929*

1919 Diseases of the Heart 87-90		1929 Diseases of the Heart 90-95	
87	Pericarditis	90	Pericarditis
88	Endocarditis	91	Endocarditis—acute
	Myocarditis (acute)		a. Specified as acute
			b. Unspecified (under 45)
		92	Endocarditis—chronic
			a. Specified as chronic and other valvular disease
			b. Unspecified (over 45)
		93	Myocarditis—acute
			a. Specified
			b. Unspecified (under 45)
			c. Myocarditis—chronic myocardial degeneration
			d. Unspecified (over 45)
89	Angina pectoris	94	a. Angina pectoris
			b. Diseases of the coronary arteries
90	Other diseases of the heart	95	Other diseases of the heart
			a. Functional
			b. Other and unspecified

It is startling, indeed, to discover that in the years 1804-1808 inclusive there were no deaths from heart disease recorded[9] in the city of New York.

It was in 1868 that a joint committee of the Royal College of Physicians, London, recognized the importance of a uniform nomenclature as a requisite for the registration of statistical facts. The registration of the deaths by causes the committee considered would give "light on the cause, hence, when recognized may be prevented, removed, diminished and treated." To recognize the cause in statistics it must be stated by the physician executing the certificate, and as yet few certificates of death contain the statement of etiology, as we understand it, of a cardiac death.

Largely through the efforts of Bertillon, some forty years ago, several countries adopted the International List of the Causes of Death. This was a step to learn numerically the size of the death injury from various causes but it was also a step toward the use of a nomenclature. Since the adoption of the list there has been a revision every ten years, but, as yet, the structural damage of the heart is considered for the most part as the cause of death and not the pathogenesis of that structural change. Thus there is a numbered paragraph for inflammation of the pericardium, of the myocardium and of the endocardium, with subheadings depending on the time factor, acute or chronic, and the arbitrary subdivision depending on age 45 (table 2). There is a number in the list for the symptomatic condition angina pectoris. There is one other number with the caption "Other diseases of the heart" which should be for the rare and infrequent diseases.

As a matter of record, however, in 1924 there were only 10.6 per cent of all heart deaths[10] in the United States contained in the three numbers, while 89.4 per cent of all the cardiac deaths were contained in the one number. In New York State in 1927[11] there were only 11.5 per cent of all the cardiac deaths in the three numbers and 88.5 per cent of the cardiac deaths in the one number. In New York State, since the 1929 revision, the inflammation of the endocardium and myocardium are rearranged under two groups with the time element of acute, chronic and age 45 as the separating classifications, but without any suggestion of etiology (table 2).

The first returns show the effectiveness of the new headings, causing a greater distribution and withholding deaths from the old number 90; for, DePorte[12] states, that "in January, 1930, 91.8 per cent of the deaths from heart disease were classed under other diseases of the heart"; but in January, 1931, only 4.3 per cent, the rest being shown under the new headings "chronic endocarditis and diseases of the myocardium."

In a study[11] of other diseases of the heart in New York State for 1922 and 1926 it was apparent that the physicians of the state could become "myocardial minded," for in 1922 chronic myocarditis was 34.1 per cent and in 1926 it was 48.6 per cent, an increase of nearly 50 per cent (table 3). Yet some ten years previously Cabot[13] found in his study of 3,000 necropsies that "myocarditis was recognized six times as often as it was present." However, about this same period, another physician[14] of international eminence had emphasized the importance of the efficiency of the myocardium and deprecated the great weight given to the valve damage. Perhaps his emphatic statement had the twofold effect of reducing the registered deaths ascribed to "valvular disease" from 23 per cent to 15.7 per cent and of increasing the assignment to myocarditis. It was almost certain that there was no such change in the actual incidence of myocarditis or valvular disease. Of these two conditions, the pathogenic agent was not stated but only the structural change. These tabular changes evidently result from the demands of "style," "vogue" or "fashion in medical thought" and the method of statistical exhibition.

Table 3.—*Other Diseases of the Heart* *

		Percentage									
Age Groups	Total Deaths	Chronic Myocarditis	Chronic Endocarditis	Valvular Disease of the Heart	Mitral Regurgitation	Mitral Stenosis	Cardiac Insufficiency	Diseases of the Aorta	Cardiac Hypertrophy and Dilation	Cardiorenal Diseases	Other Diseases of the Heart
1926

[14] Mackenzie, James: Diseases of the Heart, New York, Oxford University Press, 1908.

In New York State in 1930 the deaths from heart disease were 34,867, or 23.6 per cent of all the deaths (147,372) in the state (table 4).

Table 4.—*Monthly Vital Statistics Review, New York State Department of Health, March, 1931* [12]

New York State—1930 Classification	Number	Per Cent
Deaths	147,372	.....
New York City	74,889	.....
New York State	72,483	.....
Heart (87-90)	34,867	23.6
Cancer	15,514	10.52
Pneumonia	12,881	8.7
Tuberculosis	8,139	.....

The deaths from heart disease were only 1,667 less than the sum of all the deaths from cancer, pneumonia and tuberculosis, yet the forms of heart disease cannot be separated into the proportions of various etiology.

In 1927, in New York State, DePorte [15] made a survey of the sickness as reported by physicians from certain districts of the state. He found that the reportable diseases made up 3.3 per cent, while the nonreportable comprised 96.7 per cent of the diseases cared for (table 5). Of the nonreportable diseases of cardiovascular importance, arteriosclerosis is 3.4 per cent and the group diseases of the heart is 4.3 per cent. Acute rheumatic fever amounts to 2.4 per cent and tonsillitis to 6.4 per cent. Thus, heart disease (4.3 per cent) exceeded all the reportable diseases (3.3 per cent).

Table 5.—*Morbidity Survey in Certain Districts of New York State in 1927* [15]

	Number of Cases	Per Cent
Reportable communicable diseases	3,212	3.3
Nonreportable diseases	94,857	96.7
Total	98,069	100
Of [illegible]		Per Cent
[illegible]		6.4
[illegible]		4.3
Arteriosclerosis		3.4
Acute rheumatic fever		2.4

Recognized heart disease (4.3 per cent) alone exceeds "all reportable diseases (3.3 per cent)."

In the same study DePorte found that, of all the causes included in the morbidity survey, all nonreportable diseases equaled 94.4 per cent but the deaths in that group were 77.6 per cent. Heart disease made up 7.2 per cent of all illness but contributed 34 per cent of the deaths in the same group (table 6). All reported communicable diseases comprised 5.6 per cent but account for 22.4 per cent of the deaths.

Table 6.—*Percentage Distribution of Cases in Morbidity Survey and of Mortality in the State, Exclusive of New York City, from Specific Nonreportable, and from all Reportable Communicable Diseases* [15]

All Causes Included in Morbidity Survey	Percentage of Cases in Morbidity	Percentage of Deaths
	100	100
[illegible]	94.4	77.6
[illegible]	7.2	34.0
[illegible]	2.7	0.3
Syphilis	0.5	0.7
All reportable communicable diseases	5.6	22.4

During the year October, 1927, through September, 1928, the physicians of a single county (Essex) [12] in New York State made reports of illness and mortality to Dr. DePorte of the state bureau of vital statistics. In this study (table 7) tonsillitis was 5.2 per cent, arteriosclerosis 3.0 per cent, diseases of the heart 2.8 per cent, and rheumatism 2.1 per cent, a total of 13.1 per cent. All reportable communicable diseases comprised 1.6 per cent.

During the months January to April, 1931, cases of heart disease reported by physicians to Dr. DePorte [16] in a survey of morbidity from heart disease in New York State, exclusive of New York City, showed the age distribution given in table 8.

Table 7.—*Sickness in Essex County, N. Y., Oct. 2, 1927, to Sept. 29, 1928* [12]

Disease		Number	Per Cent
All diseases		19,179	.....
[illegible]		312	1.6
[illegible]		18,867	100
[illegible]		976	5.2
[illegible]		569	3.0
[illegible]		535	2.8
[illegible]		121	.....
Syphilitic		9	.....
Other forms	75.7%	405	.....
[illegible]		392	2.1
[illegible]		87	.....
[illegible]		305	.....
			13.1

In this study rheumatic fever [17] and chorea account for 25 per cent of all the cases, 37.3 per cent of the cases under 45 and 16.9 per cent of those over 45. Chronic hypertension occurs in one in four (25 per cent) of those over 45 years of age.

Thus, up to the present, attention has been focused by the statisticians' point of view on the spectacular communicable diseases which must be reported, but the insidious diseases which have higher incidence of illness and death cannot, as yet, be analyzed. The etiology may be obscure, it is true, but with the increasing burden of deaths is it not time to devote more attention to determining the cause? Our ignorance can be decreased by stating etiology.

Table 8.—*Cases of Heart Disease Reported by Physicians, January to April, 1931, in a Survey of Morbidity from Heart Disease in New York State, Exclusive of New York City*

	Number	All, per Cent	Under 45, per Cent	Over 45, per Cent
Total	1,281	100	100	100
Rheumatic fever	294	23	32.8	16.5
Chorea	25	2	4.5	0.4
Syphilis	52	4.1	3.5	4.5
Other infections	158	12.3	20.2	7.5
Congenital	34	2.7	3.1	2.4
Chronic high blood pressure	207	16.2	1	25.6
Thyrotoxicosis	64	5.0	6.1	4.3
Other causes	189	14.8	13.4	15.6
Etiology unknown	213	16.6	12.2	19.5
Nervous heart	45	3.5	3.3	3.7

CLINICAL

The clinician surveys the patient and builds a syndrome from symptoms and objective conditions common to a single pathogenesis and compares the structural change pathognomonic of the etiology.[18] The arrangement of the descriptive diagnosis may well follow a systematic order as follows: etiology, anatomic condition, physiologic action and the functional classification of the patient.

[18] Cohn, A. E.: Statistical Studies Bearing on Problems in the Classification of Heart Disease, Am. Heart J. **1**: 442 (April) 1926.

The case experiences of some observers have been tabulated and published and show interesting mutations in the relative proportions of the diagnoses as assigned to the etiologic factors.

In the Essex County, N. Y., study of DePorte [12] the simple classification showed: diseases of the heart, 538, or 100 per cent; rheumatism, 121, or 22.6 per cent; syphilis, 9, and other forms, 405, or 75.7 per cent.

In Boston, White and Jones,[19] in a study of 3,000 cases of heart disease divided by etiologic factors found (table 9): rheumatism, 30 per cent; syphilis, 2.9 per cent; arteriosclerosis 24.0 per cent, hypertension 22.2 per cent, angina pectoris 11.1 per cent, these three making up 57.3 per cent; effort syndrome, 9.5 per cent.

Patients seen in private practice show a distinct trend to the senescent degenerative heart condition, but patients attending the outpatient department show a much larger proportion of rheumatic damage.

In New York, Wyckoff and Lingg [20] found the conditions to be: rheumatic, 42.7 per cent; senescent, 22.2 per cent; syphilitic, 8.6 per cent, and other and unknown conditions, 26.4 per cent.

The New York cardiac clinics, a cooperative study by fifty clinics using a common nomenclature and criteria of classification, with a case load of 14,353, in 1930, closed out 3,850 cases, and the tabulated report is as follows: rheumatic etiology, 48.10 per cent; syphilitic, 5.30 per cent; senescent (arteriosclerosis, hypertension), 12.29 per cent; unknown, 21.51 per cent; other, 6.75 per cent, and congenital and multiple, 6.05 per cent, making 100 per cent.

It is noteworthy that the group having an "unknown" etiology is 21.51 per cent of the whole. One must admire the courage of observers who admit inability to discover evidence of the etiologic factor. It leaves a seductive field to be explored by more intensive clinical investigation. In these groups from different regions of the country rheumatic disease varies from 22 to 48 per cent. Some of the difference may be due to regional, age and other influences. The total group, however, is small, yet it shows a large proportion of heart damage to be due to the crippling effect of rheumatic fever.

The clinical evidence in patients with impaired hearts may reveal the process to be active or inactive, and the position in nosology indicated by one of the following in the etiologic list:[21] 1, congenital; 2, rheumatic; 3, syphilis; 4, arteriosclerosis; 5, hypertensive; 6, unknown; 7, other—specify; 8, bacterial; 9, thyroid; 10, toxic; 11, anemia 12, emphysema; 13, neurosis; 14, psychosis; 15, trauma.

It will be accepted without doubt that, for a prognosis and rational treatment of the diseased heart, a knowledge of etiology is necessary. To prevent the damage of a healthy heart it is essential also to learn the way to prevent the transmission of the infecting agent. These reasons would seem so important as to justify all the trouble it may require of the clinician to make available with the aid of the statistician the statement of the magnitude of the problem and to make it possible, too, to show the effect that therapy directed toward the etiology may have.

SUMMARY AND CONCLUSIONS

There have been presented samples of observations concerning diseases of the heart from three points of view—a series of necropsies, a series of surveys by a bureau of vital statistics, and a series of clinical studies.

The necropsies are not comparable because there was no common factor—etiology. One series is a mixture of structural changes and etiology, while the second is etiology alone.

In the statistics of mortality and morbidity, the same lack of a common denominator destroys the validity of comparison.

The clinical studies are more nearly comparable since the classification is etiology, but in one of the two sets there is contained a symptomatic class which, however, can be included bodily in the arteriosclerotic group.

It appears that an enormous amount of work has been done by all these observers in collecting these figures, but the value of the results would have been greatly enhanced by the common denominator of etiology.

The etiologic point of view has required centuries to develop, but it now pervades the profession.

The profession has demonstrated that it can change rapidly and readjust itself to the use of a changing nomenclature.

The pathologist can differentiate and give the most accurate information of the etiologic factors causing structural damage to the heart.

The statistician of vital statistics, following the International List of the Causes of Death, is as yet unprepared in thought and unable from his data to give any information as to the etiology of the damage to the heart.

The clinician has formulated, adopted and applied a nomenclature and criteria of diagnosis founded on etiologic distinctions between diseases of the heart.

At present, rheumatic disease accounts for a fifth of the deaths from heart disease coming to necropsy and for a fourth to a half of the patients under treatment.

Coronary artery disease accounts for a half of damaged hearts at autopsy and about a fifth to a half of the patients cared for by physicians.

Syphilis at necropsy accounts for less than one in ten, and less than one in twenty for the clinician.

These three important etiologic groups can be differentiated and together they comprise about three fourths of the whole problem of morbidity and mortality of heart disease.

As all diagnoses and records depend on the practitioner, the conclusion seems justified that accurate

knowledge of the extent of etiologic groups will not be available until clinicians, pathologists and statisticians think of, diagnose, treat and record the diseases of the heart by a common nomenclature of etiology whenever, wherever and for whatever purpose records are made. Let etiology become the vogue and style.

Need this take 5,000 years?

ABSTRACT OF DISCUSSION

Dr. W. H. Robey, Boston: A few days ago I happened to meet the chief of the Bureau of Vital Statistics at Washington, who told me that he had just received a diagnosis from a physician, stating that the patient had died of edema. On being informed that the mention of a symptom of that type was not sufficient to go into the records at Washington, the physician wrote back that he would not change the diagnosis—it was a very good one thirty years ago and, in his opinion, was just as good today. A short time ago I heard of a man, aged 84, who had died of mitral regurgitation. Of course, the murmur was not due to endocarditis but was the functional murmur of an enlarged left ventricle. Edema, headache, pain, and even angina pectoris are really merely symptoms. The pathologist has the best opportunity of making the correct diagnosis, but one cannot compare hospital practice with private practice in this respect. In hospitals the pathologist is at hand and the autopsy is more readily obtained than in private practice, when the physician often has to do without the autopsy and must make his diagnosis on a thorough history and physical examination. I think that some physicians are not inclined to go carefully enough into the history and are more apt to make the diagnosis on what they find in the heart; for example, a mere murmur. Mitral stenosis, for instance, is really not a disease but a symptom of rheumatic fever; likewise an aortic regurgitation may be a mere symptom, either of rheumatic fever or of syphilis. With regard to angina pectoris, there is in the minds of the present committee working on the classification of diseases a great question whether angina pectoris should be put in the list at all, it being a symptom of arteriosclerosis, of syphilis or of some other condition the etiology of which may be obtained by a careful history. In other words, statements concerning lesions in the heart which are placed on a death certificate should be qualified by the etiologic factor. A diagnosis of mitral stenosis, as I said before, should be qualified by a statement of the type of rheumatic infection which the physician thinks is the cause of it. If any progress is to be made in the therapy of heart disease and in prognosis, more attention must be paid to the etiology. Diagnosis must be made not on symptomatology but on etiology combined with a careful physical examination.

Dr. Allen H. Bunce, Atlanta, Ga.: Advance in the study of heart disease can be made only if every physician follows up his patients not only when they are alive, but also on the postmortem table. In Atlanta, at the Emory University Division of the Grady Hospital, where only negroes are treated, we have been able to obtain a large percentage of postmortem examinations. Our figures differ from those of Dr. Halsey's in that more than half of our cases are due to syphilis of the heart. Over a five-year period in a small group of private patients suffering from heart disease, we have averaged more than 90 per cent of postmortem examinations, and during one of these years we registered 100 per cent of postmortems in the group who died. Men practicing internal medicine owe it to themselves, to their patients and to the advancement of science to follow up their cases and see to it that postmortem examinations are made or, better still, to make the examinations themselves. I think that is probably the most important way in which we can advance the knowledge of heart disease. It can be done, because an enlightened public is anxious to cooperate with the doctor, and if we physicians don't do it, it is our own fault.

Dr. Robert H. Halsey, New York: Only recently have there been deaths from heart disease. From 1804 to 1808 in New York City there were no deaths from heart disease.

DELAYED LABOR CAUSED BY A SHORTENED OR SHORT UMBILICAL CORD*

JOHN P. GARDINER, M.D.
Obstetrician, Robinwood Hospital, Dispensary of Toledo District Nurse Association
TOLEDO, OHIO

In all cases of delayed labor a shortened or short cord must be suspected. In 1922 I[1] reported the analysis of 35,712 cases, which showed a shortened or short cord once in every 5.5 births. From an analysis of the last 750 consecutive cases of my own, on which the following conclusions are based, there is a shortened or short cord (a cord complication) once in every 3.5 births. The usually accepted symptoms of cord complication are: an immediate recedence of the presenting part at the end of the uterine contraction; a recedence accompanied by the passing of urine;[2] umbilical souffle;[3] a gradual cessation of labor pains;[4] pain in the back; a desire on the part of the patient to assume the sitting posture, in order to exert more pressure in expulsion; localized pain at the placental site, due to traction on the placenta and partial inversion of the fundus. During the relaxation of the contraction, the placental site remains depressed until the presenting part recedes enough for the fundus to resume its normal form.[5] In my series the most frequent symptom is a delay in labor.

It is generally agreed that the time of labor for a primipara is from sixteen to eighteen hours for the first stage and two and one-half hours for the second; for a multipara, twelve hours for the first stage and from one-quarter hour to one hour for the second. However true a guide or standard the time element of labor may be, it is not sufficient, for it in no way describes the labor. Delayed labor is an expression used in contrast to the term "normal labor." The term "normal labor" in itself is indefinite; average labor would seem to be a term of better aptitude, for it admits of the idea of progression.[6] The view that the umbilical cord complicates labor is not new but dates back even to the time of Hippocrates.[7] The usually accepted causes of delayed labor are a disproportion, dry labor, uterine inertia, thick, tough membranes, and in primiparas a rigid, elongated cervix. From my experience it is possible to contradict these usually accepted ideas given as the chief causes of delayed labor and to substitute as the most frequent cause a shortened or short cord. In this series a delay in labor occurred once in every six births, of which 66 per cent were due to a shortened or short cord. Experience tends to put me on my guard to suspect a shortened or short cord as the chief cause of any delay throughout the whole progress of labor.

At the end of pregnancy the obstetrician is concerned with the position of the fetus. If it is not in the usual position, an effort is made to determine the possible

[6] Normal has taken on the significance of perfect. One says his heart is normal, signifying that it is perfect; one's lungs are normal, meaning they are perfect. But "average" is a term of more inclusive definition. As one uses the term normal temperature, meaning average temperature, so one should use the term average lungs for normal lungs, average heart for normal heart, and average labor for normal labor.

cause. In cases of malposition it is assumed that there exists a disproportion between the fetus and the pelvic inlet. (In the few cases of monstrosities or tumor growths in the fetus or the mother, the disproportion or the obliteration of the inlet is the cause of the malposition.) I find that a cord complication is frequently the cause of a malposition. In a breech presentation, a transverse position, the head in either fossa, or a high floating head, a cord complication must be considered. It is generally agreed that it is best that labor start in a vertex presentation; so an attempt is made to convert any malposition into a head position. Oftentimes this effort at conversion, if there is sufficient liquor amnii, is rewarded with success, for the cord may be so placed as to slip along, permitting the head position. In the absence of other signs when conversion is not possible, a cord complication is no doubt the cause; it increases the gravity of the prognosis for the child. The seriousness of a malposition of the fetus due to a cord complication at the end of pregnancy is illustrated in the following case:

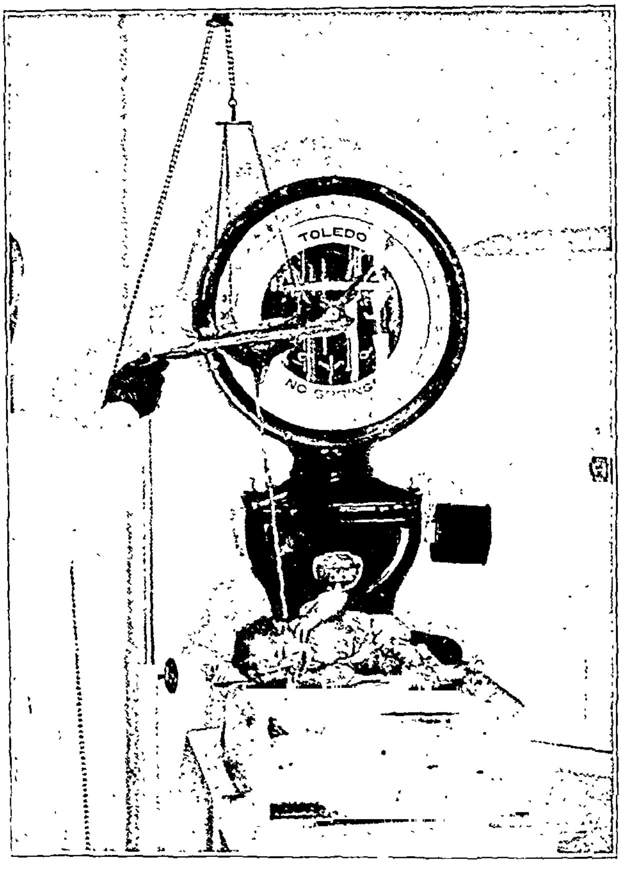

Fig. 1.—Method of estimating the traction on the umbilical cord by registering the loss of weight.

Mrs. R., a primipara, at term, entered labor with the fetus in a transverse position, which was maintained in spite of attempts at conversion into a head position. Therefore, as there were no abnormalities, the pelvis was roomy and there was a moderate amount of liquor amnii, a cord complication was suggested. The patient was permitted to go into labor but was prepared for a tentative cesarean section. The fetal heart rate was 140. Three hours later the fetal heart began to fail; there was no cervical dilatation and no change in position. A cesarean section was done immediately. The cord, with a coil about the neck, was taut from the placenta; the fetal portion ran from the umbilicus under the perineum up the back to the neck, there completing the coil. The length of the cord was 45 cm. The asphyxiated child was resuscitated, and the recovery of the mother and the child was uneventful. Though this case was observed as closely as possible, it is seen that the cesarean section was delayed almost too long.

There is little question that in many of these cases an elective cesarean section will be the easiest method of delivery for the mother, and the safest for the child.

FALSE LABOR PAINS

Just what factors are active as the primary cause of the onset of labor is not yet clearly defined. It would seem that the initiation of labor is dependent on glandular action. Substances from the placenta, the ovary and the pituitary have been extracted and tested and the consensus[8] favors the extract of the anterior portion of the pituitary body. Dubois[9] was very much interested in weakness of the labor pains and experimented with ergot but found that it was too dangerous for the child. It is probably true that the painless recurring uterine contractions or waves of pregnancy become painful at the beginning of labor. However, the painful contractions may cease, only to recur again at intervals, for days before labor starts, becoming the well established clinical phenomenon called "false labor pains." A shortened or short cord must be seriously considered, as accounting for the traction on the cord, interfering with the action of the labor-initiating substance, by preventing descent of the presenting part, thus depriving the lower uterine segment of its continuous, stimulating pressure. The following case illustrates this:

A quintipara, with relaxed vaginal outlet, fourteen days overdue, had had recurring pains in the back and in the lower part of the abdomen for six days. The head was engaged in the superior strait, back to the right, fetal heart to the left and below the umbilicus; the rate was 124. The pelvis was roomy and there was no disproportion. The cervix was soft (hydrated), patulous for 5 cm., and easily dilatable, with thick edges. During the contractions there was no progressive descent of the head. After the patient had been lying down for a few minutes the pains would cease. (A provisional diagnosis of a cord complication was made.) The patient was placed in the recumbent position, the shoulders and head were raised, and the thighs were abducted and flexed on the abdomen. In this position the contractions recurred at regular intervals. At each contraction the fetal head was pressed down on the hydrated, easily dilatable cervix, with still some recession of the presenting part at the end of the contraction. The fetal heart rate ranged from 115 to 145 and the child was of average size. After one and one-half hours of little progress, under light anesthesia, the hand was gently inserted and the cord was felt taut about the neck. An unsuccessful attempt was made to remove the cord. The membranes were ruptured and, further efforts failing to remove the cord, the forceps were applied and the head brought down to the vulva. The forceps had to be reapplied to bring the head over the perineum. The cord, buried deeply with a reversed coil about the neck, explaining the unsuccessful attempt at intra-uterine removal, was cut to relieve the traction. The placenta, preceded by a discharge of blood, followed in five minutes. The cord was 43 cm. long. It was possible to continue the progress of labor and to eliminate the "false labor pains" when the distance from the placental insertion of the cord to the point of coiling at the fetal neck was shortened, by raising the head and shoulders and flexing and abducting the thighs of the patient.

The increased muscular effort necessary to expel a child held back by traction on the cord has not been sufficiently stressed. This stretched cord was only 43 cm. long,[10] which accounts for the great traction produced. The placenta often separates, allowing the birth to take place, as happened in this case. Therefore, in a multipara with no disproportion, with the cervix open 5 cm. and easily dilatable, with an average size child, with recurring pains (false labor pains) for several days when standing but disappearing when lying down, a cord complication must be suspected, as the cause of the false labor pains, causing the delay in the onset of labor.

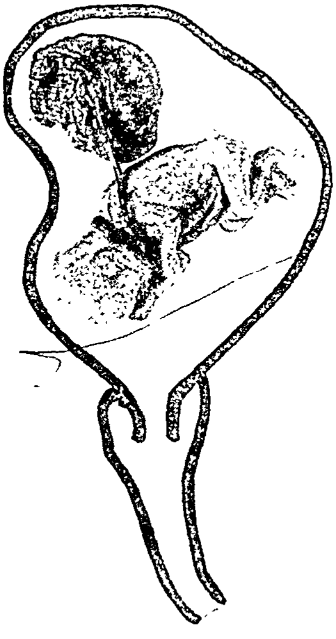

Fig. 2.—Before labor starts, in cord complications such as this, cesarean section must be considered and immediately performed if there is any variation in the fetal heart.

FIRST STAGE OF LABOR

During the first stage of labor the symptoms of a shortened or short cord are the most difficult to differentiate. Great effort is required at this time to diagnose the condition in the uterus. Once labor has begun it must progress continuously and uninterruptedly until the child is born; if it does not, the cause must be sought. It is a strange fact that the idea of a cord complication interfering with the progress of labor does not take form in the mind of the obstetrician until he is well along in experience.[11] The action of the cord is so subtle and cryptic that it baffles real diagnostic skill. Then, too, the self-evident fact revealed by a complicated cord at the very end of labor, with its surprise and with its demand for more or less immediate action, comes at the proper psychologic moment to center the attention not on the previous condition and action of the cord but on its immediate relief.

No doubt, this rather minor detail accounts for the fact that the problem has been missed, and a cord complication has not been one of general interest. In the past it has been an obstetric truism that as long as the membranes are intact the child is in no danger. There is no greater fallacy than this assumption. I have observed three varieties of cord complications which are fatal to the child in the early stages of labor, in which the membranes are intact. One is a reversed coil about the neck, the taut umbilical portion of the cord running over the placental portion at the front of the neck; during the first contractions of labor the chin is flexed on the crossing of the cord, compressing it against the sternal end of the clavicle, thus stopping the circulation of the cord and causing the death of the fetus. In another instance the vessels of the cord and placenta are so stretched by the traction on a shortened or short cord that the blood pressure is not sufficient to force the blood through, and the fetus dies. In the last a cord, caught between the fetal extremities, is compressed and obliterates the fetal circulation, as frequently happens with a large fetus or with one in which the labor is overdue. (There is still another form of shortened cord which produces a delay in the progress of labor: a cord with plications resembling the mesentery. The plications affecting a greater or lesser portion of the cord, causing the cord to be shortened, tear when there is sufficient traction. Logically a rupture should occur, but I have never been able to determine one from this cause.)

Matthews Duncan[11] became interested in the complications of the umbilical cord and went so far as to perform some experiments. He tested the strength of the cord and found that it would withstand a weight of about 8 pounds before rupturing. I have repeated this experiment and have found that some cords will bear a weight of 10 pounds or a little over, for a short time before rupturing. It is significant that the cords usually rupture at some point along their course. (While the weights were on, tension was noticed at the union of the cord and the placenta. Here the amnion folds were straightened out and the fibers were heard to crackle.) The umbilical vein seems to be the first to rupture, the jelly of Wharton ruptures, and the two arteries resist longest. The expulsive force of the uterus and the abdominal muscles reaches a pressure of about 50 pounds.[12] The resistance of the birth canal is equal to this pressure; however, the resistance is not required to be overcome at one time but by degrees. The pressure during the first stage of labor is much less while the uterus is acting alone.

In order to determine the amount of retardation, if any, occasioned by the slipping of the cord about the neck, a living child was placed on the scales with the cord coiled about the neck. It was found that the slipping of the cord about the neck caused a loss of over 7 ounces. It can readily be seen that a half-pound retardation from the slipping of the cord, in the first stage of labor, may have a very definite effect. In delayed labor, because the cord is long at birth, it cannot be taken for granted that there was no traction, causing the delay. It may be pointed out that the umbilical cord seen at birth is a dying or dead cord and not the virile, expansile cord of late pregnancy. As long as its circulation is maintained, the cord does not slip along as readily on itself as does the dead, relaxed cord. This is proved by the fact that a cord with a true knot, unless there is great traction, rarely gives rise to any trouble from compression; seldom is there tightening of the knot by sliding on itself, except

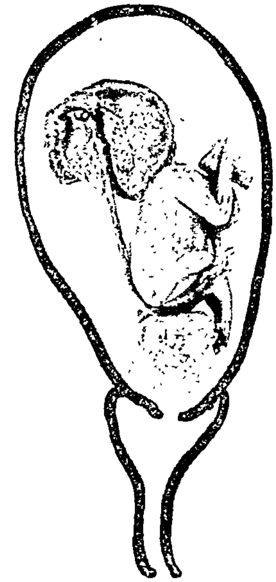

Fig. 3.—Near the end of the first stage of labor, the membranes still intact. Not only will traction on the cord cause delay, but the narrowing, because of the increased tension, may overcome the blood pressure in the umbilical vessels.

---

[10] I have pointed out in a previous paper[1] that a cord, without producing traction, having a coil about the neck, must be 93.5 cm. long to allow the birth of the child. Kunze (Zentralbl. f. Gynäk. **51**: 1832-1838 [July 16] 1927), in 12,000 cases of coiling, found that the average length was 66.5 cm. The comparison gives a very good idea of the frequency of traction in cord complicated cases.

[11] Duncan, Matthews: Tr. London Obst. Soc. **23**: 243, 1882. King: Tr. Am. Gynec. Soc. **11**: 485-491, 1889; Am. J. Obst. **26**: 307-319, 1892, **14**: 322-328, 1881.

[12] Braun von Fernwald: Wien. med. Presse **21**: 41, 1880.

after death, for the lateral expansion, caused by the blood pressure in the live cord, prevents it. If this non-slipping or limited slipping is true of the knot, it is even more true of a coil or loop about the neck where the space is limited, as the cord is more or less compressed during labor, between the chin and the chest, and, further, the skin is more resistant to the slipping than is the cord on itself.

In determining the amount of pull necessary to affect the descent, a living child weighing 6 pounds 10 ounces was placed on the scales. The cord, still attached to the child and to the placenta, was coiled once about the neck. When the placenta was lifted up, the scales registered a loss of 3 pounds 6 ounces before the pull would turn the child over. (It was possible to lift the child off the scales by raising the placenta. There was no sign of tearing at the umbilicus, placenta or in the cord.) In making an effort to duplicate the condition of the cord before birth, the cords of three children were clamped at the umbilicus and the vessels filled with fluid. (The injected cord lost 1 cm. in length in every 10 cm.) When the latter experiment was repeated by putting each child on the scales with the cord around the neck, there was a loss of a half to a pound more weight when the cords were filled than when the cords were relaxed, which would tend to prove that during labor there is more resistance from an active cord than from a relaxed cord after birth. The degree of delay varies directly with the amount of slipping of the cord, as the resistance increases the traction, especially during the first stage of labor when the expulsive force is not so great. A cord coiled about the neck may, then, be sufficiently long of itself, but, with most of its length on the umbilical side of the coil at the neck and with the placental side so short as to cause traction, delayed labor may result. The relation of the resistant to the expulsive force determines the progress of the labor.

There is never a time in any obstetric case when it is not necessary to know the rate of the fetal heart.[13] But in delayed labor, as the child is already in danger, it is inexcusable not to have constant knowledge of the fetal heart action throughout the entire course of the labor, since one is warned by that alone of approaching death. The only sign in some multiparas that a delayed labor exists and that a shortened cord is the cause is a slowing of the fetal heart rate. (The woman expects the labor, judging from her previous labors, to be over in three hours; all things tend to confirm her expectation, but, after six hours of active contractions, the birth is not yet completed. The fetal heart may give the only explanation.) The treatment to render depends on the condition of the cervix. If the cervix has not fully dilated and the mother is a primipara, at the first indication of a lowering of the fetal heart rate a cesarean section must be performed. However, in the case of a multipara near the end of the first stage or in the second stage of labor, with a hydrated, easily dilated cervix, the vaginal canal may be dilated, the dilation of the cervix completed and the child delivered. Whatever method is used, the child should be delivered within twenty minutes after the disturbance of the fetal heart rate is noticed.

SECOND STAGE OF LABOR

It is during the second stage of labor, or the very last of the first, that there is the greatest infant mortality as a result of cord complications. If these children are to be saved, the fetal heart must be observed very closely. One should be well trained in differentiating the intestinal sounds from the sounds of the fetal heart beat; especially is this a difficult matter when the fetal heart sounds are distant or when there is an increase in the mother's heart rate to 120 or 130. We are now passing through a period of "labor assisting"; to what it will lead, only the future will show; it has, however, already made a contribution to the field of obstetrics. Just as the work done on the pelvis by Michealis[14] and Litzmann,[15] Waldeyer,[16] Walcher,[17] Williams[18] and many others gave the impetus for better pelvic measurements, preparing the way for Sanger's work on cesarean section and the improvements that have followed for overcoming the difficulties at the pelvic inlet, so the study of the causes of delay in labor is preparing the way for the procedures which have for their purpose the shortening of the second stage of labor: Kristeller's[19] combination of expression and extraction, De Lee's prophylactic forceps and episiotomy, and Potter's podalic version. This era of "midwifery assisting" must not be confused with the usual interpretation of "accouchement forcé." "Labor assisting" has as its aim the protecting of the vital reserve of the mother, by warding off exhaustion from delay of labor and the making more certain the delivery of a live child. Frist[20] feels that early separation of the placenta is an important symptom in cord complications and suggests that the delivery be ended by forceps when the head can be reached, accouchement forcé when the cervix is 5 cm. dilated, and in other conditions cesarean section.

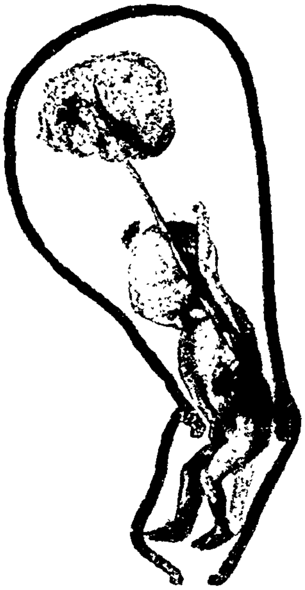

Fig. 4.—An extremely dangerous position for the child. With the cervix fully dilated and the arms of the fetus extended (especially in a primipara) there is great danger from compression of the cord, when the extended arms are brought down to allow the passage of the head through the cervix.

In the last and most readily recognized group of cord complications delaying labor, a coil or loop about the neck of the child is seen after the birth of the head. Of this condition a great deal has been written, for which much credit is due the early German obstetricians.[21] The trachea, by the embedded cord, and the fetal chest, by the structures of the lower birth canal, may be so compressed that, for the safety of the child, the cord must be cut to allow the completion of the birth. It is not good practice to pull, especially a taut cord, over the head of the child, as the vessels may be torn at the umbilicus and needless anxiety caused.

Traction in shortened or short cord cases frequently causes neonatal asphyxia, with its potential possibilities. The fetal heart, if beating regularly at from 120 to 160 at birth, will continue one-half hour before it stops. I find four forms which admit of convenient classification: There is the narcotized child, whose condition is due to the sedative used during labor, in which case it is necessary to keep the lungs well aerated until respiration becomes regular. The asphyxiated child, whose condition is due to compression of the cord, is usually born in light asphyxia, asphyxia livida. A few are born in whom the heart is beating but who do not take the first gasp for from fifteen to twenty minutes. Also in this group is included the child in whom no heart beat is obtainable at birth but who with difficulty is resuscitated. To the third group belong those children whose hearts are beating and in whom *immediately after birth the accessory muscles of respiration* move violently, at intervals, but no air is taken into the lungs and thirty minutes later the heart has ceased beating. Necropsy reveals complete congenital atelectasis. To this group also belong those who are resuscitated but in whom the respiratory excursion is not full. Expiration is accompanied by a gentle, audible murmur. Enough of the lung is functioning to carry on, in some cases, for from ten to fifteen hours; then, as the red blood cells decrease, the respiratory surface is not great enough to carry on respiration, and, because of insufficient oxygen, the child becomes cyanotic; in the bronchi accumulates thick tenacious mucus, and in spite of artificial respiration and the administration of carbon dioxide the child dies. Other children will react and live. The other malformations which are incompatible with life may be included in this group. The fourth group of children appear to be asphyxiated but are suffering from the pressure of cerebral hemorrhage. The children may be dead at birth or die immediately after birth or may be resuscitated only to die later, as the hemorrhage increases; or the hemorrhage may be small, and the child be resuscitated and live. From this last group the lesson learned is to eliminate all strenuous methods of resuscitation.

SUMMARY

If there is a delay in labor due to a shortened or short cord with an interference in its circulation, there is great probability that, unless at the first sign of fetal distress some action is taken, the child will not be alive at the end of labor; the practice of obstetrics is thus in the class of emergency work. During the prenatal care period the family should be made to realize that any obstetric case is a potential emergency. There is a growing appreciation of this fact and maternity hospitals are increasing in number. The obstetrician must educate the delivery room group to realize that success in the treatment of these emergency cases is the speed under control with which the treatment can be given. The obstetrician, the delivery room group and the family must become emergency-minded if the needs of the child are to be adequately met. Everything must be in readiness to carry out the treatment decided on at a moment's notice. If the fetal heart shows signs of failure a cesarean section, a forceps application, or a manual delivery (depending on the progress of labor) should be begun. This technic is a strain on any obstetric service, but if the modern hospital is to keep pace with the development of obstetrics it must meet the requirements with intelligent and sympathetic assistance. The symptoms of shortened or short cord have been generally disregarded, for the reason, no doubt, that they are indefinite and, too, because they have not been adequately correlated.

CONCLUSION

The most definite and pronounced symptoms of a shortened or short cord are delayed labor and a *slowing of the fetal heart*.

2455 Collingwood Avenue.

ABSTRACT OF DISCUSSION

Dr. Edward A. Schumann, Philadelphia: I feel that the shortened cord is a rather unusual disturber of labor, and the actually short umbilical cord, that under 40 cm., is quite unusual indeed. Sometimes, also, I feel that the cord around the neck acts rather as a prophylactic against asphyxiation, particularly in cases of difficult delivery in which the cord, instead of causing injury, is protected from pressure by being about the neck of the child. The most important point of Dr. Gardiner's paper is the treatment of cord complications, and the treatment of these conditions must depend not so much on the obstruction to labor as on the effect on the fetus. If then, as the result of careful and continuous auscultation of the fetal heartbeats, the child is found to be in difficulty and is threatened with asphyxia, I quite agree with the speaker that immediate delivery should be performed. The method is unimportant. If the cervix is sufficiently dilated and effaced, forceps or version may properly be used. If, however, complete effacement of the cervix is not present and dilatation offers any hint of difficulty, I should certainly, in the interests of the child, advocate cesarean section by a competent obstetrician in a competent hospital. That leads me to express another thought, the importance of fetal indication for cesarean section. Too often one regards only the maternal indications and permits a woman to go through the entire period of her gestation and the difficulties of labor, only to deliver a dead child as a result of a disinclination (in the interests of the child alone) to intervene by abdominal delivery.

Dr. Philip F. Williams, Philadelphia: I should like to cite three cases to substantiate what Dr. Gardiner has said and to bring forth one further complication that may arise. A secundigravida, whose first child had been delivered by forceps in the South and who was referred to me on her removal North, entered labor at term. It was evidently a false labor, and she left the hospital and went home. She came back a few days later for reexamination. The head was not engaged. On using the Hilles method of pressing the head into the pelvis, I found that the child evidenced his displeasure by strong fetal movements. Repeating the maneuver several times and listening to the fetal heart rate, I found a marked slowing. A short umbilical cord was suspected, cesarean section was done, and a live baby was delivered with three coils of cord about his neck. In a second patient, a husky young colored primipara of 18 in labor for twelve hours, with the head in the midpelvis, delivery by forceps was attempted, a pathologic short umbilical cord was present, and traction ruptured the cord at its attachment to the placenta. A profuse hemorrhage followed and necessitated the removal of the placenta manually in order to control the hemorrhage. In the third patient, an octigravida, the membranes had ruptured and the head was in the inlet. There was a history of previous normal deliveries. An injection of solution of pituitary was given to hasten the labor. In that instance an almost precipitate delivery followed during the stormy pains produced by the solution of pituitary. The cord was coiled about the neck twice, and the placenta came out with the child. The child was stillborn, and the woman had a profuse postpartum hemorrhage, evidently resulting from the abruptio placentae produced by traction on the cord. That necessitated packing. The latter two cases show that postpartum hemorrhage from one or the other circumstance, tearing the cord at the placenta or postpartum hemorrhage in a multigravida, may follow rupture of the cord, produced by traction on a short cord or a pathologically shortened cord.

HORSESHOE KIDNEY WITH ESPECIAL REFERENCE TO SURGICAL TECHNIC

REPORT OF CASES [*]

HOWARD S. JECK, M.D.
NEW YORK

Much has been written on the subject of horseshoe kidney, especially from the standpoint of its preoperative recognition, but no summary seems to have been made of operative technic appropriate to cope with the various anomalies encountered.

Therefore, in addition to reporting statistics from Bellevue Hospital showing both the postmortem and the surgical incidence of the condition, it seemed worth while to note the anomalies that are usually associated with horseshoe kidney and to discuss especially the operative methods of dealing with them. A brief discussion of the subject in general is also given.

The incidence of horseshoe kidney has been variously estimated from autopsy observations at from 1 in 300 to 1 in 1,100. In 16,735 autopsies performed at Bellevue Hospital during the past twenty-six years, twenty-six horseshoe kidneys were found, or 1 for each 643 cadavers. This is a somewhat higher average than is usually cited.

A. R. Thompson [1] states that according to autopsy statistics compiled by him the life span of the individuals having horseshoe kidneys is relatively short. Excluding patients who died in the first year, he found that 35 was the average age at death. In the Bellevue autopsy records, the age at death varied from 4 days to 75 years. Excluding the first year deaths, the average age was 43.

The following anatomic variations have been pointed out by various authors: [2] The isthmus connects the lower poles in about 90 per cent of cases and the upper poles in 10 per cent. But Renton [3] cites a case in which the two kidneys were united by renal tissue arising from the posterior part of the left kidney, both poles being distinct and unattached. In fusion of the upper poles, the suprarenals also may be fused. Such a case is cited by Kelly and Burnam.[4] Of added interest in this case is the fact that the aorta and vena cava passed in front of the isthmus. Two cases are reported in which the isthmus was found behind the aorta, and according to Colston and Scott [5] it lies between the large vessels in 10 per cent of cases.

Histologically, the isthmus may be composed of (1) fibrous tissue alone, (2) renal cortex alone, or (3) the entire renal parenchyma.[4]

The cortical isthmus is the one most frequently encountered. Robinson [6] believes that the fibrous isthmus exists in about 15 per cent of cases, but Thompson did not find it at all in his series of nineteen horseshoe kidneys examined post mortem.

Many authors cite instances of reduplication of the ureters and the pelves. The ureter may enter the parenchyma with little or no tendency to pelvic formation, and a few cases have been reported in which the ureter entered the isthmus. In these instances the pelvis was either lacking entirely or was only rudimentary in character.[5]

With reference to the blood supply in horseshoe kidneys, Kelly and Burnam make the following statements:

> The arterial branches enter the parenchyma mostly behind the pelvis. We find the arteries coming from the aorta either in one common trunk arising below the mesenteric arteries with several other smaller branches from the iliac arteries or else two separate trunks similar to the normal renal arteries only at a lower level. Besides these, however, there are nearly always smaller twigs coming from below and behind, derivations of the external iliac, internal iliac, etc.

In all the Bellevue cases found at autopsy, fusion of the two kidneys was by means of an isthmus connecting the lower poles. The most striking and most valuable observation in the cases, from a clinical standpoint, was that in one, otherwise typical of the majority of horseshoe kidneys, only one ureter, the left one, could be found. In this case death occurred at the age of 60. Other such cases have been reported, notably two by Thompson [1] and one by Thacher.[7]

DIAGNOSIS

Before the days of urography, a preoperative diagnosis of horseshoe kidney was comparatively infrequently made. Occasionally the condition was recognized by palpation (presumably in thin individuals) of an elongated, transversely running, suprapubic tumor which represented the isthmus. In a few instances, the shadow of the isthmus or of one kidney or both kidneys, with the isthmus shadow in whole or in part, suggested the preoperative diagnosis. In other instances, the proximity of the shadows of renal calculi to the spinal column was the only guiding factor in the recognition of the anomalous condition. And in still fewer instances the condition was suggested by Rovsing's sign; namely, continuous abdominal pain which is relieved on lying down.

But once urography made its appearance, the number of cases of horseshoe kidney recognized before operation rapidly increased, and now that hardly any examination of the upper urinary tract is considered complete without a urogram, the preoperative recognition of horseshoe kidney has almost become the rule.

Since the year 1918, approximately 400 kidney operations of all kinds have been performed in the Bellevue Urological Service. In this number there were four patients with horseshoe kidneys; the anomalous condition was recognized before operation by means of pyelograms in two of them. There were no postoperative deaths. At the time of the operation in the first case of this series, although urography was known it was not carried out as a routine measure. The diagnosis was made at operation. In the third case of the series, in which operation was performed only a few months ago, the preoperative diagnosis of horseshoe kidney was also missed. This patient appeared to be so sick on admission to the hospital that a complete urologic study was not deemed advisable. As will be shown in the case report which follows, it was felt that the patient's condition demanded an emergency operation.

What are the urographic characteristics on which a diagnosis of horseshoe kidney is based or which, at any rate, should arouse one's suspicions as to the presence of such an anomaly? A majority of the authorities agree on the following:

1. Kidney pelves which are closer to the midline and lower than those of normally placed kidneys.
2. Shortening of one or both ureters, not otherwise explained.
3. A tendency of the calices to point downward or toward the vertebrae.
4. In stereoscopic urograms an anterior curve of the ureters, due to the passing of the ureters in front of the isthmus.[5] This would naturally not apply to the small percentage of cases in which the ureters lie posterior to the isthmus.
5. Calices of bizarre shapes, absence of calices, or calices overlapping the pelvis.[8]
6. Bilateral roentgen catheter shadows which show first a curve outward from and then inward toward the vertebral column at their upper extremity.

Another point, mentioned by Wright in his discussion of two cases reported at the 1931 meeting of the American Urological Association, is the break in the continuity of the psoas outline shadow.

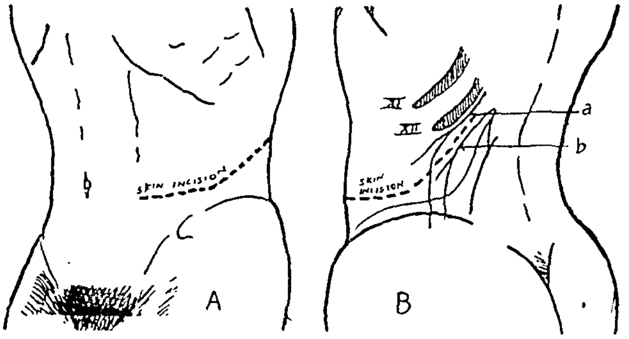

Fig. 1.—Skin incision (dotted line) for extraperitoneal approach to kidney. Note descending branch of the twelfth thoracic nerve (*a*), which usually crosses the incision; *b*, iliohypogastric nerve.

There seems to be little doubt that the unfortunate possessor of a horseshoe kidney is more liable than the normal individual to the onslaughts of certain ills that may befall humanity. This idea, however, is opposed by some. Apart from Thompson's and our own Bellevue autopsy statistics, which show the average age at death to be in the neighborhood of 35 or 40, the anatomic variations peculiar to horseshoe kidney would certainly seem to foster certain diseases of the kidney, especially those of a surgical nature. Included among these anomalies there are three that stand out preeminently:

1. Insertion of the ureter high into the kidney pelvis, which is usually found in an anterior position.
2. The passage of the ureter across the isthmus.
3. The presence of numerous aberrant vessels as a part of the blood supply.

To these may be added a fourth: viz., congenital ureteral stricture, mentioned by Eisendrath and his collaborators. But whether or not this condition is more common in the case of horseshoe kidneys than in normal kidneys is a question.

In pointing out the pathologic conditions most frequently encountered in operating on horseshoe kidneys, one can do no better than to cite the statistics of Eisendrath, Phifer and Culver. In 132 operative cases, collected by them up to July, 1925, they found the following various lesions and their incidence: renal calculi, 51; hydronephrosis, 34; tuberculosis, 13; pyonephrosis, 7. To these they added 11 cases in which operation was performed for pain alone and 16 unclassified cases. In these cases the different operations together with the number of times they were performed are as follows: heminephrectomy, 63; pyelotomy or nephrotomy, 35; symphysiotomy alone or combined with other operations such as pyelotomy, 12; pyelotomy or nephrotomy plus secondary heminephrectomy, 10; plastic operations or ureterolysis, 4; miscellaneous, 5.

Operations for the surgical conditions found in horseshoe kidneys are much the same as those for the same conditions found in congenitally normal kidneys. There are, however, certain variations in operative technic, certain anatomic difficulties to be surmounted and certain pitfalls to be guarded against. In order to save space, an attempt has been made to mention the surgical principles on which the actual technic of all different types of horseshoe kidney operations is based rather than to give a detailed description (except in a few important instances) of the actual technic itself.

The operator who has the preoperative knowledge that he is dealing with a horseshoe kidney is in a far better position to perform with facility and ease whatever operation may be necessary than he who stumbles on such a condition accidentally. To be forewarned is to be forearmed. This applies particularly to the surgical approach. By far the greater number of surgeons who have had considerable operative experience in horseshoe kidneys prefer the extraperitoneal to the transperitoneal route. With the employment of an adequate incision, the extraperitoneal approach has the following advantages:

1. Less likelihood of infecting the peritoneum, especially when dealing with tuberculosis, pyonephrosis or infected hydronephrosis.
2. Less likelihood of infecting the peritoneum, in cases of pyelotomy or nephrotomy or in heminephrectomy, should the stump of the isthmus subsequently secrete urine.

By an adequate incision for the extraperitoneal approach is meant one that will enable the operator to deal freely with the upper pole of the kidney and at the same time will permit of extension downward and forward in order to give free access to the lower pole and the isthmus. Such an incision is one which begins about 1.5 cm. below the last rib at a point about 5 cm. back from the tip of the rib, unless the rib is an unusually short one, in which case the incision is begun correspondingly farther forward. The incision is then carried forward and downward almost parallel to the border of the rib until it reaches a point about 3 cm. above the highest point of the iliac crest. Here it is carried transversely forward to a point midway between the axillary line and the outer border of the rectus muscle (fig. 1). If additional room is needed, as may be necessary for an adequate exposure of the isthmus of the kidney, it may be carried to the outer border of the rectus or even farther. The loin muscles, anterior abdominal muscles and fascia transversalis are split in the line of the skin incision. One usually encounters a descending branch of the twelfth thoracic nerve, which diagonally crosses the incision. When possible, this should be dissected free and retracted backward, since cutting or injuring the nerve may result in an area of anesthesia or hernia.

---

[8] Rathbun, N. P.: Notes on the Clinical Aspects of Horseshoe Kidney, J. Urol. 12: 611-626 (Dec.) 1924.

Fischer[9] advises resection of the twefth rib as a routine measure, but the majority of operators do not find this necessary.

Eisendrath suggests that the peritoneum be displaced while the patient is in the lateral position, and that the patient then be changed to a supine position in order better to expose the pelvis and isthmus. This plan appears to be advantageous.

In contemplating heminephrectomy, the operation most frequently necessitated by the pathologic conditions found in horseshoe kidneys, the operator should first satisfy himself in regard to the following:

1. The function and size of the other half of the kidney.
2. Whether or not the other kidney has its own separate ureter.
3. Presence of accessory arteries and veins.
4. Whether or not the kidney which is to remain has ample blood supply.
5. The size and composition of the isthmus.

The first point concerning the ability of the supposedly normal kidney to support life is usually determined, of course, before the operation begins. Only in emergencies in which time or the condition of the patient has not permitted this point to be settled may it become necessary to get some idea of the size of the kidney by means of palpation. Not infrequently the operator is enabled to do this by extending his hand retroperitoneally across the midline. In other instances, it may become necessary either to make a separate extraperitoneal incision in the opposite flank or, what is better, to extend the transverse part of the original incision far enough forward to permit of exploration intraperitoneally. But, as Judd[10] has pointed out, it may even then be difficult to determine whether there is a sufficient amount of tissue which is capable of maintaining proper renal function. Therefore, if still in doubt about the opposite kidney, one should employ only conservative measures in dealing with the diseased kidney. At a later date, if a subsequent study of the opposite side should warrant it, the diseased kidney could be removed. To ascertain whether or not a ureter connects with the opposite kidney pelvis, it may be necessary to make an extraperitoneal loin incision over that kidney.

The third and fourth points dealing with blood supply are exceedingly important. Accessory vessels, especially the arteries, should be sought for, since failure to ligate any of them may result in a very embarrassing hemorrhage. This applies also to vessels which may come from below (iliac or mesenteric arteries) and enter the isthmus.

In ligation of the renal pedicle, care should be taken to see that the vessel or vessels tied do not supply the only branch to the half of the kidney which is to remain. In 13 per cent of sixty cases studied at autopsy, Robinson found a single arterial trunk for the isthmus, which divided, one branch supplying the right and the other the left renal mass.

Finally the isthmus should be carefully examined to determine as far as possible its relative parenchymal and fibrous tissue content. Since the great majority of the isthmuses are made up altogether of renal parenchyma, one should play safe when in doubt by considering the isthmus parenchymatous.

Division of the isthmus is usually the most difficult and in most instances likely to be the only difficult part in performing a heminephrectomy. Various methods are suggested. If the isthmus is wholly fibrous or contains only a small amount of kidney parenchyma, two clamps are applied on either side of the proposed line of incision, the isthmus is divided, and a continuous whipover stitch of catgut is employed over the clamp on the remaining segment, just as is done in the old hemorrhoid operation. Should there be oozing on withdrawal of the clamp, it is readily enough controlled by transfixation sutures or a ligature placed around the stump *en masse*. Whenever feasible it is well to cover the stump with renal capsule; if this is not possible a piece of muscle or fat should be sutured over it.

At times the isthmus is found to be as large as any other part of the horseshoe and composed entirely of renal parenchyma. Here one's difficulties may be manifold. In such a case it is obviously difficult to set down any hard and fast rules as to a course of procedure. Kümmell[11] recommends making a wedge-shaped incision just beyond the proposed place of severing the kidney while an assistant makes firm compression on each side. He then brings the lips of the incision together by a deeply placed reef knot suture and then along the edges employs continuous catgut.

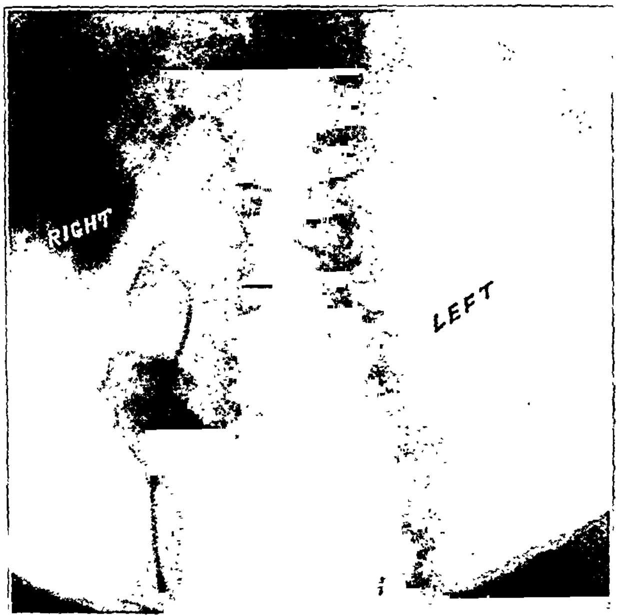

Fig. 2.—Note proximity of the lower end of the lower pelvis to vertebral column and partial rotation of kidney.

Scholl[12] only recently reported a case in which he employed the wedge-shaped incision for heminephrectomy in a case of calculous pyonephrosis. The isthmus was 5 cm. in diameter and was wholly parenchymatous. After closure of the kidney wound, a part of the capsule and surrounding fat were sewed over the stump. There was no subsequent urinary drainage.

If the isthmus is not too large and is sufficiently mobile, clamps may be applied and the bleeding controlled by the method suggested in dealing with the fibrous isthmus. Should there be any difficulty in inserting sutures preparatory to removal of the clamp on the remaining stump, it would seem advisable to leave the clamp in situ as suggested by Judd. He recommends leaving the clamp for a few days, "when the patient is large and there is considerable infection."

[12] Scholl, A. J.: Horseshoe Kidney, California & West. Med. **33**: 745-746 (Oct.) 1930.

In one of our cases we employed the actual cautery for dividing the isthmus. However, in this particular instance the isthmus was largely fibrous and consequently almost any method would have served to control the hemorrhage. The cautery has been used also by Eggers[13] and other operators in dividing the parenchymatous isthmus.

In division of the isthmus one should remember that a renal calix may, though doubtless rarely, extend into this part of the horseshoe. Papin[14] accidentally incised a calix in this location. After the stump had been sutured, a reexamination of the pyelogram showed that the aberrant calix extended beyond the section through which he had cut. Following the isthmus farther, Papin discovered a second indentation through which he made his second incision. Israel[15] mentions the likelihood of causing a urinary fistula by cutting through a calix in the isthmus. But he warns against dividing the isthmus short of normal tissue, especially when dealing with tuberculosis and cancer.

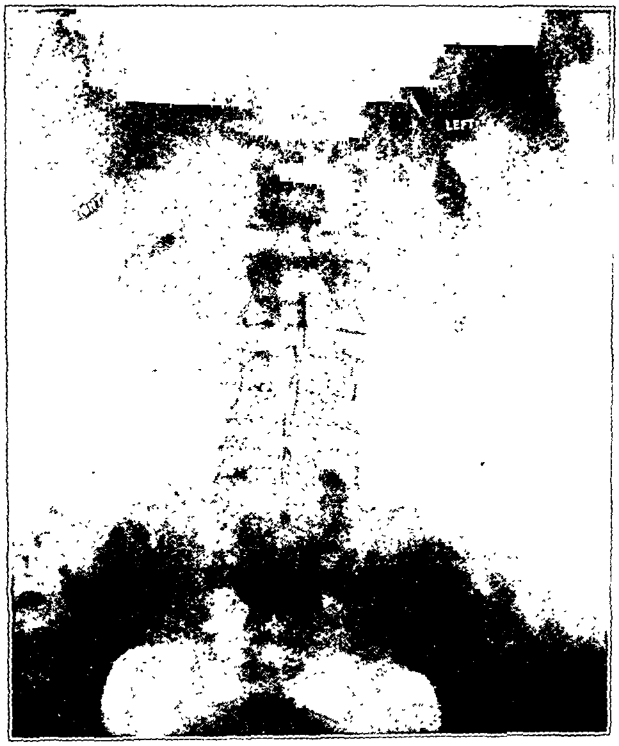

Fig. 3.—Intravenous urogram. Note presence of four pelves, two on each side.

In heminephrectomy of the rare upper pole fusion type of horseshoe kidney, it is well to remember that the suprarenals may also be fused. The dire consequences of complete suprarenalectomy need only be mentioned. It is also well to bear in mind that one may mistake at operation a fused kidney for a horseshoe kidney. Two ureters on the same side should suggest the former.

In heminephrectomy, because of the short pedicle and fixation of one pole (usually the lower), the operation may be made much easier by first emptying a distended pelvis of its contents (stone, pus or urine). This gives more room, renders the pedicle longer and enables one to clamp the pedicle with less danger of accidentally including the aorta or vena cava in the clamp. (Case 3 exemplifies this procedure.)

As for pyelotomy, nephrotomy and operations on the upper ureter, the precautions concerning accessory vessels are the chief ones to apply.

Extra care should be taken to control hemorrhage in performing pyelotomy or nephrotomy, especially the latter, for if a secondary operation should become necessary for the control of hemorrhage, it is likely to be more hazardous than the same operation primarily performed. (This is illustrated by case 4.)

In pyelotomy the incision is usually made anteriorly because this is the part of the horseshoe kidney pelvis ordinarily the more accessible. It is well to close the pyelotomy wound as securely as possible because of the possibility of extravasation of urine. Here the tendency of the extravasated urine to cross the midline of the body would obviously be greater than in a similar operation on the congenitally normal kidney.

Finally, a case reported by Swan[16] would be well to remember when dealing with intractable hemorrhage. His patient, having fallen on a horizontal bar, tore the lower pole and isthmus of the right half of a horseshoe kidney, discovered at operation. His chief symptom was hematuria. Because the kidney was too deep to suture easily and attempts to deliver it made the bleeding worse, Swan plugged the wound with gauze. When the gauze was removed three days later, there was no bleeding.

REPORT OF CASES

Case 1.—Since this case, which represents the first horseshoe kidney encountered during the period covered by the Bellevue statistics, was reported in detail by me[17] in the *International Journal of Surgery* in 1919, only the essentials are given in the following: A preoperative diagnosis of left pyonephrosis had been made in F. S., a man, aged 31. The presence of a horseshoe kidney was not discovered until the kidney had been thoroughly exposed by the oblique loin extraperitoneal incision. Heminephrectomy was performed. The isthmus, chiefly fibrous and about the size of one's thumb, was divided at its narrowest portion between two clamps. The stump was sutured, before the clamp was removed, with a whipover stitch, such as is employed in the clamp and suture hemorrhoid operation. No bleeding followed the removal of the clamp. Convalescence was uneventful.

Case 2.—In this case a preoperative diagnosis was made from the pyelogram. Heminephrectomy was performed because of suppurative pyelonephritis.

E. D., a man, aged 21, was admitted to the Bellevue Urological Service, May 1, 1923, on account of nongonorrheal left epididymitis. A few days after his admission, pain and tenderness developed in the right loin. A pyelogram on the right side disclosed two pelves and two ureters. Since bilateral pyelograms were made with much greater reservation at that time than they are today, the urogram of the left side was omitted. Because of the proximity of the lower pelvis to the vertebral column and because of the position of the calices, we believed we were dealing with a horseshoe kidney (fig. 2). Specimens from both pelves on the right side showed pus cells, those from the upper pelvis being in clumps while those from the lower pelvis were only scattered. The left ureteral specimen likewise showed a few scattered white blood cells.

[17] Jeck, H. S.: Horseshoe Kidney, Internat. J. Med. Surg. **32:** 239 (Aug.) 1919.

The urea output from the three pelves was as follows: upper right, 15 Gm. per liter; lower right, 9 Gm. per liter; left, 5 Gm. per liter. Indigo carmine showed up in deep concentration from the ureter leading to the upper right and the left pelves but in only medium concentration from the ureter to the lower left pelvis.

Because of the continued rise in temperature and tenderness in the left loin, operation on the left kidney was decided on. Under gas-oxygen anesthesia the left loin oblique and transverse kidney incision (as described in the foregoing) was made. As soon as the kidney was exposed, it was carefully palpated, and the preoperative diagnosis of horseshoe kidney was confirmed. The lower pole could readily be felt extending across the median line, and the opposite kidney could likewise be palpated.

The kidney was found to be flabbier than normal, and its cortex was studded with miliary abscesses. One abscess, however, was fully the size of a large pea. It was decided to remove the right half of the kidney. In this case the heminephrectomy was accomplished with very little difficulty. The main blood supply came from under the ribs and entered the upper pelvis near the upper pole. Other blood vessels entered the lower pelvis, which was the larger of the two, coming from below upward. These were smaller than the upper blood vessels. All blood vessels were clamped and ligated, and the isthmus, which appeared to be mostly fibrous in character, was divided at the narrowest point of the toe of the horseshoe. A clamp was first placed across the isthmus just to the right of the proposed line of incision and the isthmus was cut. Before the clamp was removed, the cut edge was sutured by means of the whipover stitch described in case 1. This was pulled tight as the clamp was withdrawn. There was no bleeding. A cigaret drain was inserted, and the wound was closed in layers.

The patient's convalescence was somewhat stormy because of an infection of the superficial tissues about the wound, but he finally made a complete recovery.

Case 3.—Diagnosis of horseshoe kidney was made at the time of operation. G. M., a West Indian, aged 22, was admitted to the Urological Service, Feb. 4, 1931. He complained of pain in the left loin and also in the left lower quadrant. He was passing urine every three to four hours by day and about twice at night. It is interesting to note that, while the pain was chiefly in the left loin, it radiated at times across the abdomen.

On admission his temperature was 100 F. and soon rose to 103. He was apparently suffering a great deal and at times vomited. Although it was difficult to palpate his left loin successfully, so intense was the tenderness, it was thought that a fairly large mass could be felt. The urine contained a little albumin, some granular casts, and a few white and red blood cells. A diagnosis of perinephric abscess was made, but an emergency flat roentgenogram was not particularly helpful in confirming this. It was felt that, if a catheterized specimen of urine from the left kidney was free from pus, a diagnosis of perinephric abscess would be more or less confirmed. It was also felt that the patient was too sick to have more done at the time of cystoscopic examination than catheterization of the ureters and the making of an indigo carmine test.

On cystoscopic examination the bladder seemed to be normal. Indigocarmine appeared from the right ureter in deep concentration in seven minutes. No indigo carmine could be seen coming from the left ureter. Catheters were introduced up both ureters, the right one going only 8 cm. and the left one 20 cm. A specimen was obtained from the right ureter but none at all from the left. The right ureteral specimen showed 6 Gm. of urea per liter and was negative for pus.

At the time of the operation the patient's temperature had dropped almost to normal and the pain in the left loin had abated considerably. The loin was also much less tender than on admission. At this time a diagnosis of infected hydronephrosis seemed more probable than perinephric abscess.

The usual left oblique transverse loin incision was made. A very large, more or less lobulated, fluctuating shell of kidney soon presented itself. Because the kidney mass filled the entire wound there was some difficulty in freeing it from the adhesions which bound it down. Finally the kidney was freed except at the lower pole. Here it seemed to taper off into a dense sort of mass, which would not give way. On further palpation it was soon discovered that this tapering end extended across the spinal column. It was not until then that the presence of a horseshoe kidney became evident.

In order to afford more room, the kidney pelvis was tapped and at least a pint of thin pus and urine was evacuated. The kidney readily collapsed, which made the rest of the operation relatively easy. Heminephrectomy was considered as the operation of choice. The problem of whether or not the right side of the kidney had its own ureter then arose. The appearance of indigo carmine from the ureteral orifice on the right side at the time of cystoscopy was not considered as sufficient proof that the right kidney was large enough to carry on the work of two. The roentgen shadow was not plain enough to be reassuring, and very little information as to the size of the kidney could be elicited by palpating across the spinal column. The patient was too sick to permit of much further exploring. Therefore it was decided that on account of the infection it would be safer to take for granted the functional capacity of the right kidney and to do a nephrectomy than to leave the infected mass in situ.

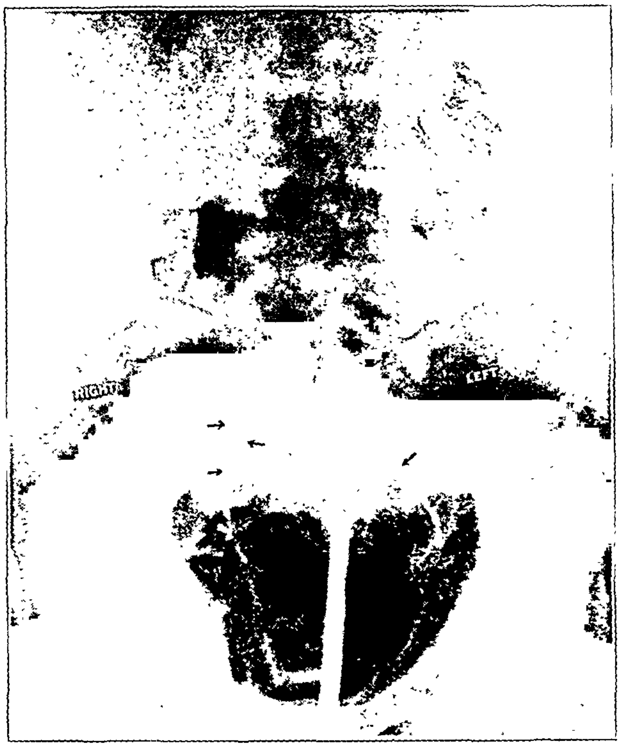

Fig. 4.—Retrograde urogram of patient shown in figure 3. The arrows indicate outlines of two ureters on the left side and a Y-shaped ureter on the right side.

The left half of the kidney and the isthmus were then thoroughly examined for accessory blood vessels and ureters. With the exception of two or three aberrant arteries entering the lower pole, no other vessels were seen. On the left side there was apparently only one ureter. This was as large as one's little finger and entered the pelvis in fairly normal fashion, although there was some narrowing at the ureteropelvic junction. The ureter was clamped, ligated and cut about 4 inches below this point. The pedicle and accessory vessels were then clamped, tied and cut. This then permitted free access to that part of the isthmus where the division was to be made. The entire left kidney was so hollowed out by the infected process that it was not difficult to determine where the point of division should be. The actual cautery was employed in cutting off the diseased portion of the kidney, the slight oozing which resulted being readily controlled by the cautery. No sutures or ligatures at all were used to control any bleeding from the stump.

Two cigaret drains were inserted in the wound, and the loin muscles were closed in layers. Convalescence was uneventful and there was never any drainage of urine from the wound.

Case 4.—R. M., a man, aged 24, an Italian, reported to the Urological Department of the Cornell Clinic in January, 1931, complaining of pain in the right upper quadrant. A diagnosis of a small stone in each half of a horseshoe kidney was made. This case was interesting in that the first urogram made disclosed the presence of two pelves and two ureters on the left side. A similar condition was suspected on the right side but was not proved until later. Because of the fact that his pain was not particularly severe and was even absent a good deal of the time, plus the fact that the stones were evidently very small and therefore likely to be difficult to remove, he was advised to defer operation until such time as it might become absolutely necessary. Toward the latter part of March the pain in the right loin became so persistent and so nagging in character that he entered the Urological Service at Bellevue for the purpose of having the stone in the right kidney removed.

At Bellevue, interest was at once directed toward the proof of two pelves and two ureters on the right side. This was finally accomplished by employing both intravenous and retrograde urography. In one of the plates made by the former method, four pelves were fairly distinctly seen, but no ureters (fig. 3). In other plates by the latter method, two ureters on the left side and one ureter on the right side were distinctly outlined, with a strong suggestion of a second ureter on the right side (fig. 4).

The stone on the right side appeared to be in one of the minor calices of the lower pelvis.

April 8, 1931, the patient was operated on,[18] the usual incision being employed. Palpation of the kidney mass soon confirmed the diagnosis of horseshoe kidney, and careful dissection proved the presence of two ureters on the right side. The isthmus appeared to be about as large as one's thumb and composed of kidney parenchyma entirely.

As was expected, there was considerable difficulty in locating the stone. Not until the lower portion of the pelvis was opened (anteriorly) and the little finger inserted could the stone finally be detected. It lay in one of the minor calices. Since attempts to remove it with forceps through the pelvic opening were unsuccessful, it became necessary to cut through the cortex immediately over the stone. The stone was then removed readily through the cortical wound.

The wound in the cortex, which was scarcely longer than 1 cm., was closed with one through and through mattress suture, bits of fat being placed in each loop before the suture was drawn taut. Two mattress sutures were then placed over the incision through the kidney capsule. The pelvic incision was partially closed by one suture placed in the lower angle. Two cigaret drains were led down to the pelvis and brought out in the middle of the wound. The muscles and skin were closed in layers.

A few days after the operation, blood appeared in the voided urine. In twenty-four hours' time it had disappeared, then in another twenty-four hours it reappeared, and cystoscopy disclosed the fact that bloody urine was coming from the right kidney. The hematuria was so persistent that eight days after the operation a transfusion was performed, 500 cc. of blood being given. As the bleeding still continued and the patient was losing ground, a second operation was performed, April 19, eleven days after the first operation, with the idea of controlling the hemorrhage, probably by nephrectomy. Under spinal anesthesia the patient's old wound was opened up. The following is Dr. Stevens' [19] description of the secondary operation: "The patient's condition was precarious. It seemed that his best chance for life was in the rapid removal of the right kidney. Hence both ureters were cut across and tied; the vessels at the two poles were similarly treated; two vessels going into the region of the upper pelvis were likewise cut and tied, and the veins running parallel to the ureters were cut between ligatures. This freed the right kidney very well, but the problem of how to handle the excision from the left kidney was a serious one as there seemed no way to control the bleeding coming from the left kidney. Venous bleeding had been encountered from the region of the upper pelvis with some loss of blood, and the patient could ill afford to lose any more. Hence several through and through sutures of number 2 chromic catgut were deliberately placed through the kidney below the lower pelvis, and this region of the kidney was tied off *en masse*, as one would tie a large pedicle, three of these sutures being used at first. The kidney was then quickly cut away more than a centimeter above these sutures. Two other sutures were similarly placed afterward to control two oozing points."

The postoperative convalescence was stormy. The patient suffered considerable shock as a result of the operation, and the wound soon showed evidence of a marked infection. However, his condition slowly improved, and at the present writing he is about ready to be discharged from the hospital, although some urine still leaks through a small fistula in his loin.

(Note.—June 25, 1931, a third operation was performed on this patient because of the persistence of a urinary fistula in the loin. The old incision was reopened and continued transversely across the midline. Both an extraperitoneal and an intraperitoneal exposure were required in order to find the stump of the isthmus. When finally located, a small segment of it was removed because of infection. July 26, the patient was discharged from the hospital. While the wound was not quite healed, no urine had leaked through it since the time of the third and last operation.)

SUMMARY

The incidence of horseshoe kidney taken from autopsy records at large varies from 1 in 300 to 1 in 1,100. The Bellevue autopsy incidence is 1 in 643.

The average age at death of individuals with horseshoe kidneys is probably in the neighborhood of from 35 to 40 years.

Since 1918, in approximately 400 kidney operations in the Bellevue Urological Service, there were four cases of horseshoe kidney. Two of these were encountered during the first five years of this period and two during the last five months. Two were recognized as horseshoe kidneys before operation and two were not. In three of the cases, heminephrectomy was performed. Of these three, the pathologic condition encountered in two was pyonephrosis and in the other suppurative nephritis. In the fourth case small bilateral calculi were present. Pyelotomy and nephrotomy were performed on the right side for the removal of a stone, and a few days later a secondary heminephrectomy became necessary because of hemorrhage. Several weeks later a portion of the stump was removed because of a persistent urinary fistula and infection of the stump.

Heminephrectomy was relatively easy in the first three cases. In all three the isthmus was small and chiefly fibrous in character. Accessory blood vessels were also present in all three but were easily recognized. In the fourth case, heminephrectomy was difficult partly because it was a secondary heminephrectomy but chiefly because of the large size and histologic character of the isthmus. This was first tied with transfixation sutures and then divided.

CONCLUSIONS

1. Horseshoe kidneys are more prone to become diseased than normal kidneys. The surgical diseases are doubtless due to poor pelvic drainage fostered by certain anatomic anomalies.

2. A preoperative recognition of horseshoe kidney before the days of urography was exceptional. Today its recognition, except in emergency cases, has almost become the rule.

---

[18] Dr. A. R. Stevens, who operated on the patient, furnished the details concerning the operations and gave me permission to include the case among these reports.

[19] Stevens, A. R.: Personal communication to the author.

3. Greater care in the various types of operations on horseshoe kidneys must be exercised than in similar operations on congenitally normal kidneys. The factors rendering such precautionary measures necessary are (*a*) the extensive and anomalous blood supply, (*b*) the possible presence of the two ureters on the same side, (*c*) the size and character of the isthmus, (*d*) the relative immobility of the kidney, and (*e*) the possibility of the presence of the rarer anomalies, such as fusion of the suprarenals.

4. The knowledge that the supposedly sound half of the kidney has its own ureter intact is essential before performing a heminephrectomy. This operation is rendered much easier by an incision (preferably extraperitoneal) which permits of ample exposure of the kidney pelvis, the isthmus and all possible accessory vessels.

REGURGITATION RENAL COLIC

A CLINICAL ENTITY *

BRANSFORD LEWIS, M.D.
ST. LOUIS

In former years the medical profession rested serene in its reliance on the integrity and constancy of the normal ureteral valve for resisting and preventing the regurgitation of fluid from bladder to ureter. Once it had entered the bladder there was no going backward, even under all the pressures or provocations that could be brought to bear to that end. Experiments on animals served to confirm this belief.

In 1898, Young[1] was unable to effect regurgitation by various degrees of pressure on the filled bladders of animals, and he affirmed the correctness of the established belief. The researches of Sampson and of Stoeckel pointed in the same direction.

But clinical observations of Kretschmer, Kelly and others, and the numerous experiments of Graves and Davidoff, Bumpus, Zernblinoff, Guyon and Albarran, Icobelli, Lewin and Goldschmidt, Marcus, von Lichtenberg, Lampe, Warschauer, Alksne and Barbey changed the views of the profession. Graves and Davidoff[2] showed that even under very low pressure (from 8 to 10 mm. of mercury) the slow filling of the bladder in healthy dogs, cats and rabbits was followed by a surprisingly large percentage of regurgitation into the ureters of the opaque fluid used, proved with roentgenograms. In rabbits it was as high as 80 per cent. The authors found that it was the stronger bladders having the greatest tonicity that were most likely to do the backward leaking, while those possessing less tonicity were most likely to show a competent and resisting valve.

These striking results in animals naturally were followed by the question of their bearing on human beings and their ureteral orifices. Bumpus[3] endeavored to get an answer to this question and made 1,036 cystograms in patients, finding 89 (8.6 per cent) in which there was regurgitation into one or both ureters, some connected with back pressure, others in which the open and incompetent valve was made so by participation of the ureteral wall in inflammatory processes that involved primarily the bladder. So that it now seems well established that, under appropriate conditions of tonicity and pressure on the filled or semifilled bladder, urine or fluid does regurgitate through the healthy and intact ureteral orifice back into the ureter and up even to the renal pelvis. Colored fluids (aniline dyes) were made thus to ascend the ureteral channels. Antiperistalsis played no part in the phenomenon.

By experiments and minute investigations, Gruber[4] endeavored to learn the exact mechanism, whether sphincteric or valvular, by which regurgitation was ordinarily prevented. His definite conclusion was that the intravesical ureter served as a passive true valve and not as a sphincter. Cutting or injury to the valve permits regurgitation, and stretching the bladder mucosa by injecting into the bladder excessively large amounts of fluid under high pressure shortens the valves and in many instances renders them incompetent. Regurgitation in health is thus again confirmed.

The main deduction made from these observations by practically all writers was that it offered obvious explanation as to the frequency of ascending infection from bladder to kidney: It was simply carried thence by infected urine regurgitating under conditions favorable for it.

But a careful and exhaustive review of current textbooks on urology, as well as of the writings of the authors quoted, has failed to reveal any reference to urinary regurgitation as a cause for renal colic.

With the phenomenon of renal colic, physicians are well acquainted, the suddenness and severity of the attack precipitating an apparently healthy individual into torture that rolls him on the floor in agony and requires large doses of morphine to bring about relief.

If the colic is due to stone, naturally suspected, it is, of course, the physician's duty to recognize the cause and remove it as promptly as may be. But in many instances, even with the suffering as great as described, there is no stone present and an entirely different course of treatment is to be pursued, dependent on the cause of the colic in that particular case.

It is generally recognized that renal colic or pain that closely simulates it is caused by a number of different conditions other than the presence of stone in the ureter or kidney pelvis. Henry Morris,[5] for instance, mentions as causes hysteria, renal congestion from nervous excitement, perinephric abscess, menstrual disturbances, torsion of renal vessels or ureter, strain, cicatricial bands pressing on ureter or kidney, aneurysm of the descending aorta, biliary and appendicular disorders, vesical calculi or new growths, ureteritis, seminal vesiculitis, movable kidney, Dietl's crisis, renal tuberculosis, and urine overcharged with uric acid or with oxalate of calcium crystals. In addition to these, periodic attacks occur, he says, in cases without being followed by the discharge of a calculus. They come on without any ascertainable cause, especially when the patient falls into low health or is worn out by prolonged or fatiguing occupation. As to the severity of suffering, he says: "Women have aborted, men have committed suicide and children have been thrown into convulsions during the fearful agony of renal colic."

* *From the St. Louis University School of Medicine.*

* Read before the Section on Urology at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 12, 1931.

* The term "urinary reflux" refers to the easy passage of urine back and forth between the bladder and the ureter through a wide-open "golf-hole" orifice. "Urinary regurgitation" relates to the passage of urine from the bladder to the ureter through a normal, intact ureteral orifice under the influence of overfilling or of an undue amount of pressure on the filled or semifilled bladder.

Kelly and Burnam[6] discuss nephralgia as connected with hematuria caused by three conditions: (*a*) nephritis, (*b*) varices of the kidney pelvis, and (*c*) rupture of small blood vessels. They assert that, in a number of instances (over 100), operations, including nephrectomy, had been carried out without disclosing any cause for either hematuria or colic, and in some operative cases pain only was present without hematuria.[7]

This declaration indicates two points deserving attention: (1) the lengths to which renal colic drives the practitioner as well as the patient on occasion, and (2) the necessity of knowing and having at one's command all the possible causes for this condition in order that one may promptly fulfil the requirements of correct diagnosis and successful treatment.

Keyes[8] has lucidly analyzed the several conditions and sequences attendant on urinary retention, partial and complete, temporary and chronic, but has not mentioned severe renal colic as an accompaniment of them. He refers also to the occasional occurrence of reflux of fluid up the ureter during cystography in animals, and reasons that the same phenomena may occur in man. The most interesting deduction he makes from it, he says, is its bearing on infections of the upper tract, urethral chill, and so on. Under the caption "Pseudorenal Colic," Keyes says:

> I have reported cases in which the passage of crystals or blood clots from the kidney, intestinal colic and vesiculitis precisely resembled renal colic in their subjective symptoms. Many physicians cherish the delusion that such pseudorenal colics are not as intense as the colics due to stone and do not require morphine. But in intensity there seems little choice between them.

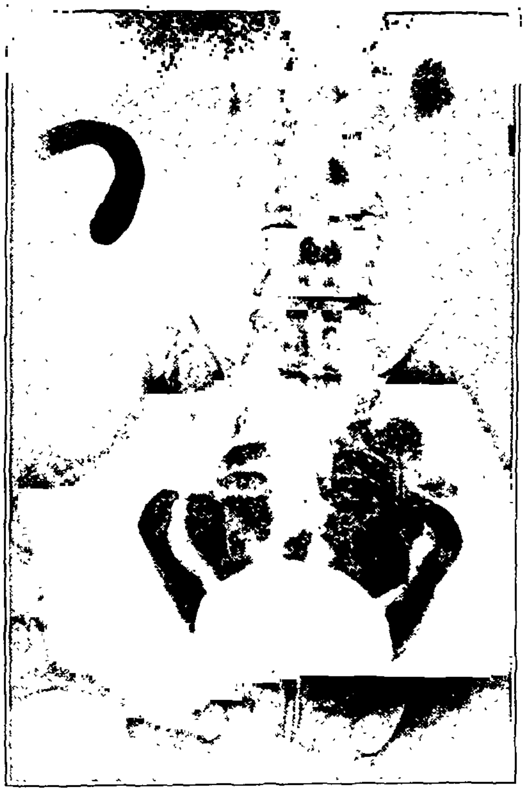

Fig. 1 (courtesy of Dr. P. E. McCown of Indianapolis).—Cystogram showing bilateral regurgitation in case presenting prostatic obstruction and chronic right renal pain. Relief was afforded by prostatectomy.

Francis Kidd[9] contributes an enlightening chapter on renal pain and hematuria of unknown origin, mentioning numerous causes, but urinary regurgitation is not "among those present."

Casper[10] gives a formidable list of causes other than stone for renal colic but does not mention urinary regurgitation in that light. The same might be said of other authors consulted, Eugene Fuller, Thomson Walker, Guitéras, Victor Pedersen, Henry Morton, Ballenger, David Newman, Chetwood, Cabot, Young, Green and Brooks, and others. Hence the inference either that regurgitation renal colic has not received any recognition on the part of the profession or that it is deemed so insignificant that it does not deserve such recognition. The latter is hardly conceivable, in view of the expressions quoted and the sufferings entailed.

The acute and agonizing suffering from typical renal colic, recurrent for months or years or protracted for days, should certainly be of sufficient importance to deserve or demand the attention of the profession, however incidental it may be to other and greater pathologic conditions.

That the phenomenon of renal colic caused by urinary regurgitation has previously been called to the attention of the profession appears from the fact that I[11] have discussed the subject in that light in papers in 1924, 1925, 1926, and occasionally in impromptu discussions of medical societies since 1915.

In the paper of 1926 was related the fact that as early as 1913 I had been impressed with the association between urinary obstruction at the vesical neck and renal colic. Several striking and typical cases had, in the years following, come under my observation, some of which were briefly related. My earlier interpretation of the relationship was that of nervous reflex from obstructed bladder to kidney; that is, vesicorenal reflex; and it was not until the experiments of Graves and Davidoff[2] and of Bumpus,[3] confirmed by others, divulged the frailty instead of the reliability of the ureteral valve that I understood the reason for the relationship. Regurgitation through the intact ureteral orifice occurred under back pressure in a strong bladder blocked by prostatic obstruction, whether from contracture or from overgrowth!

The newly established facts harmonized wonderfully with clinical observations made in previous years. They explained to my satisfaction why intense renal colics, recurrent or enduring, occurred in direct connection with prostatic obstruction in men and urethral obstruction in women (whether organic or spasmodic), and why relief was immediate and complete on draining the bladder, and was made permanent by following up with measures that removed the obstruction. At any rate, some clinical evidence is here submitted, the early cases previously quoted being included. These cases are given in brief outline, many details of examination, history, and so on being omitted for the sake of brevity.

REPORT OF CASES

Case 1.—Nov. 18, 1913, a physician patient, Dr. F. J. D., aged 59, arrived from Dallas, Texas, referred by Drs. Kinsell and Martin of that city. He had been suffering for about fifteen years from recurrent attacks of pain in the back on the left side, the pain running thence down the course of the ureter. In addition there was pain in the bladder and perineum, with extreme sensitiveness on urinating and in intercourse, lasting at times for hours. The suspicion of ureteral stone awakened by these persistent symptoms appeared to be confirmed by roentgenograms taken in Dallas (without being checked up with the ureteral catheters, however) which showed a shadow apparently in the line of the left ureter, low down.

The urine was loaded with blood, pus and bacteria. But roentgenograms, taken with catheters placed in the ureters, showed the supposed stone shadow to be outside the ureter, and that there was therefore no stone; while the evidence of obstruction and irritation at the vesical neck was clear, including as it did a small amount of residual urine (2 ounces) and supersensitiveness of the urethra and the bladder.

Although of fifteen years' standing, the symptoms were promptly cleared up, and relief was attained by treatment directed to the obstruction and inflammation located at the neck of the bladder: Kollmann dilatings were given, together with antiseptic posturethral irrigations.

This case was so striking that it made an impression that lasted. Several other cases seen later renewed the impression of prostatic obstruction causing "stone colic" without the stone.

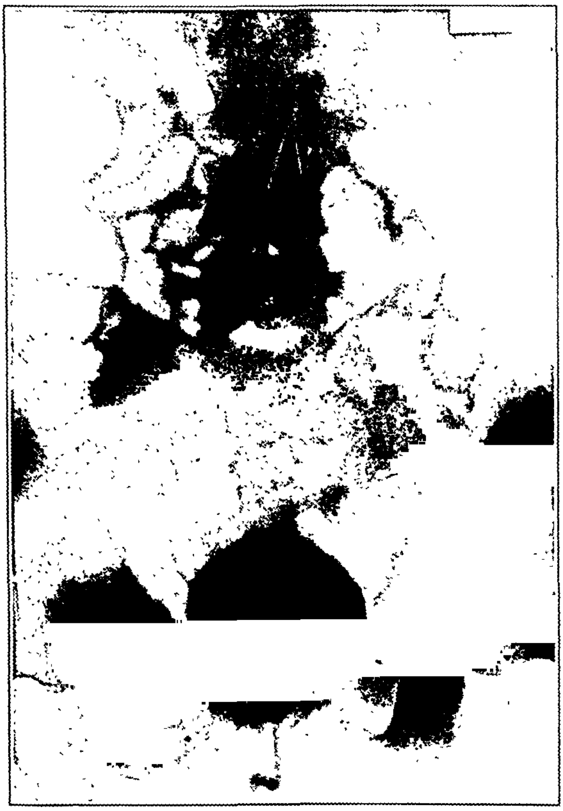

Fig. 2 (courtesy of Dr. P. E. McCown of Indianapolis).—Chronic renal pain, unaccountable until cystogram showed regurgitation (above) and dilations gave relief.

Case 2.—N. E. G., a man, aged 55, a musician of Granite City, Ill., was referred in October, 1920, by Dr. R. W. Binney of that city. While marching and playing in a parade he suddenly experienced excruciating pain in the side and back, following down the course of the ureter. He fell out of line and was given emergency treatment by Dr. Binney, who at once became convinced that the colic was caused by a ureteral stone in transit. Considerable morphine in repeated hypodermic doses was required to give even temporary relief. My investigation disclosed the presence of 7½ ounces of residual urine produced by obstruction (contracture) at the vesical neck, and the patient then stated that there had been for months an increasing difficulty in urination, with frequent straining efforts.

Roentgenography with ureteral catheterization demonstrated the absence of stone at any point as clearly as those agencies were capable of doing, and treatment for relief of the obstruction (indwelling catheter, dilatings, and so on) was given at once and permanently relieved the pain. Efficient urination was reestablished and retention done away with by Kollmann dilatings and irrigations, which were given with decreasing frequency during the ensuing few months. There has been no recurrence of the pain. I have never seen a more typical attack of renal colic than this patient had presented.

Case 3.—F. W. O., a man, aged 61, married, a manufacturer, of Alton, Ill., first consulted me, Feb. 23, 1921. Of robust health and tireless energy, and engaged in the manufacturing business on a large scale, the patient was accustomed to drive his faculties to the limit, incidentally ignoring as far as he could the natural demands made on him; he would frequently go from early morning until night without urinating. Nevertheless he had no urinary complaint until three years prior to our first interview of 1921. During those three years he observed some gradual slowing of the stream, with sluggishness increasing to actual interference both in starting and in continuing but no increase in frequency. His bladder continued to be trained to tolerate the retention of urine for long periods, in response to the exigencies of business responsibilities.

February 18, five days before our first conference, while on the train coming from the East, he noticed that difficulty of urination was worse than usual and continued so; and on the morning of February 23 there was added for the first time severe pain in the lower portion of the abdomen, described by him as beginning about the left inguinal region and running up along the course of the ureter to the kidney. He had to leave his place of business for home, where he received two hypodermics of morphine from his family physician, Dr. Joesting, before obtaining relief from the renal colic. Dr. Schaff also was called in conference. In addition to the severe pain there was nausea and vomiting.

I was called and saw him early on the same afternoon. While I was impressed with the simulation of kidney stone colic in the symptom complex, a question mark was injected into the situation when I found 8 ounces of residual urine in the bladder, turbid and infected. The patient was immediately referred to the hospital, where the usual measures of examination were systematically carried out: cystoscopy and roentgenography. The bladder was so inflamed, sensitive and resistant that cystoscopy was difficult and the ureteral orifices were not observed. The urinary obstruction appeared to be from contracture rather than from intravesical hypertrophy. No shadows showed in the several roentgenograms.

A soft rubber catheter had been left in since the first call of the day before, and this had given immediate and complete relief from the renal colic present.

An independent observation of the nurse was impressive; namely, that in irrigating the bladder the ureteral colic was excited and was complained of each time that much fluid was injected, but that it was promptly relieved on releasing the fluid. Following the retained catheter regimen, which gave effective drainage of the bladder, there was complete cessation of the colic; and in the nine years since then, in which the patient has been more or less under observation and care, the only recurrences of the pain have been in connection with holding the urine too long and consequent unusual difficulty in evacuation. The patient has not wished to undergo any radical operative procedure.

Case 4.—H. K., a trained nurse, aged 25, first consulted me in 1913. After a dinner with champagne and a long automobile ride in which no opportunity was presented for evacuating the bladder there was acute retention of urine with spasms of straining, accompanied by severe pain that seemed to run upward along the ureter to the right kidney. After repeated unsuccessful efforts at urination, the attack continued until relieved by catheterization, by which about 20 ounces of urine was withdrawn. Successive similar attacks during the next few days had again to be relieved by catheterization, and each was suffering, he says: "Women have aborted, men have committed suicide and children have been thrown into convulsions during the fearful agony of renal colic."

Kelly and Burnam[6] discuss nephralgia as connected with hematuria caused by three conditions: (*a*) nephritis, (*b*) varices of the kidney pelvis, and (*c*) rupture of small blood vessels. They assert that, in a number of instances (over 100), operations, including nephrectomy, had been carried out without disclosing any cause for either hematuria or colic, and in some operative cases pain only was present without hematuria.[7]

This declaration indicates two points deserving attention: (1) the lengths to which renal colic drives the practitioner as well as the patient on occasion, and (2) the necessity of knowing and having at one's command all the possible causes for this condition in order that one may promptly fulfil the requirements of correct diagnosis and successful treatment.

The suspicion of ureteral stone awakened by these persistent symptoms appeared to be confirmed by roentgenograms taken in Dallas (without being checked up with the ureteral catheters, however) which showed a shadow apparently in the line of the left ureter, low down.

The urine was loaded with blood, pus and bacteria. But roentgenograms, taken with catheters placed in the ureters, showed the supposed stone shadow to be outside the ureter, and that there was therefore no stone; while the evidence of obstruction and irritation at the vesical neck was clear, including as it did a small amount of residual urine (2 ounces) and supersensitiveness of the urethra and the bladder.

Although of fifteen years' standing, the symptoms were promptly cleared up, and relief was attained by treatment directed to the obstruction and inflammation located at the neck of the bladder: Kollmann dilatings were given, together with antiseptic posturethral irrigations.

This case was so striking that it made an impression that lasted. Several other cases seen later renewed the impression of prostatic obstruction causing "stone colic" without the stone.

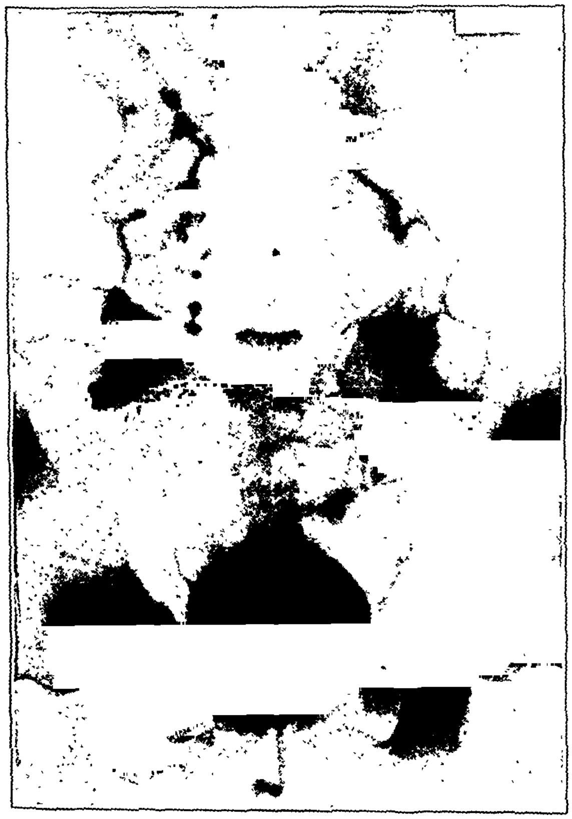

Fig. 2 (courtesy of Dr. P. E. McCown of Indianapolis).—Chronic renal pain, unaccountable until cystogram showed regurgitation (above) and dilations gave relief.

Case 2.—N. E. G., a man, aged 55, a musician of Granite City, Ill., was referred in October, 1920, by Dr. R. W. Binney of that city. While marching and playing in a parade he suddenly experienced excruciating pain in the side and back, following down the course of the ureter. He fell out of line and was given emergency treatment by Dr. Binney, who at once became convinced that the colic was caused by a ureteral stone in transit. Considerable morphine in repeated hypodermic doses was required to give even temporary relief. My investigation disclosed the presence of 7½ ounces of residual urine produced by obstruction (contracture) at the vesical neck, and the patient then stated that there had been for months an increasing difficulty in urination, with frequent straining efforts.

Roentgenography with ureteral catheterization demonstrated the absence of stone at any point as clearly as those agencies were capable of doing, and treatment for relief of the obstruction (indwelling catheter, dilatings, and so on) was given at once and permanently relieved the pain. Efficient urination was reestablished and retention done away with by Kollmann dilatings and irrigations, which were given with decreasing frequency during the ensuing few months. There has been no recurrence of the pain. I have never seen a more typical attack of renal colic than this patient had presented.

Case 3.—F. W. O., a man, aged 61, married, a manufacturer, of Alton, Ill., first consulted me, Feb. 23, 1921. Of robust health and tireless energy, and engaged in the manufacturing business on a large scale, the patient was accustomed to drive his faculties to the limit, incidentally ignoring as far as he could the natural demands made on him; he would frequently go from early morning until night without urinating. Nevertheless he had no urinary complaint until three years prior to our first interview of 1921. During those three years he observed some gradual slowing of the stream, with sluggishness increasing to actual interference both in starting and in continuing but no increase in frequency. His bladder continued to be trained to tolerate the retention of urine for long periods, in response to the exigencies of business responsibilities.

February 18, five days before our first conference, while on the train coming from the East, he noticed that difficulty of urination was worse than usual and continued so; and on the morning of February 23 there was added for the first time severe pain in the lower portion of the abdomen, described by him as beginning about the left inguinal region and running up along the course of the ureter to the kidney. He had to leave his place of business for home, where he received two hypodermics of morphine from his family physician, Dr. Joesting, before obtaining relief from the renal colic. Dr. Schaff also was called in conference. In addition to the severe pain there was nausea and vomiting.

I was called and saw him early on the same afternoon. While I was impressed with the simulation of kidney stone colic in the symptom complex, a question mark was injected into the situation when I found 8 ounces of residual urine in the bladder, turbid and infected. The patient was immediately referred to the hospital, where the usual measures of examination were systematically carried out: cystoscopy and roentgenography. The bladder was so inflamed, sensitive and resistant that cystoscopy was difficult and the ureteral orifices were not observed. The urinary obstruction appeared to be from contracture rather than from intravesical hypertrophy. No shadows showed in the several roentgenograms.

A soft rubber catheter had been left in since the first call of the day before, and this had given immediate and complete relief from the renal colic present.

An independent observation of the nurse was impressive; namely, that in irrigating the bladder the ureteral colic was excited and was complained of each time that much fluid was injected, but that it was promptly relieved on releasing the fluid. Following the retained catheter regimen, which gave effective drainage of the bladder, there was complete cessation of the colic; and in the nine years since then, in which the patient has been more or less under observation and care, the only recurrences of the pain have been in connection with holding the urine too long and consequent unusual difficulty in evacuation. The patient has not wished to undergo any radical operative procedure.

Case 4.—H. K., a trained nurse, aged 25, first consulted me in 1913. After a dinner with champagne and a long automobile ride in which no opportunity was presented for evacuating the bladder there was acute retention of urine with spasms of straining, accompanied by severe pain that seemed to run upward along the ureter to the right kidney. After repeated unsuccessful efforts at urination, the attack continued until relieved by catheterization, by which about 20 ounces of urine was withdrawn. Successive similar attacks during the next few days had again to be relieved by catheterization, and each was accompanied by renal pain incident to the retention. The urine was at first clear but soon became cloudy with colon bacillus infection.

Urethral dilatings (Kollmann) and irrigations gave prompt recovery and no recurrence.

Case 5.—Mrs. E. T., aged 41, was referred July 27, 1929, by Dr. Rutledge, Festus, Mo. So severe was the pain in the suprapubic and left lumbar regions, accompanied by straining efforts at urination but complete retention excepting the occasional passage of a drachm or so of urine under the severest straining, that she entered the hospital on a stretcher. The attack had been in progress since the previous five days. One similar attack had been experienced three years earlier, with almost complete retention for forty-eight hours.

Catheterization was extremely difficult because of a strictured urethra, together with a benign growth in the urethra. Fulguration of this growth, followed by Kollmann dilatings, restored normal urination and as promptly relieved the excruciating lumbar pain. From this time until October, 1930, the patient neglected the follow-up treatment and then had a recurrence of difficult urination, straining and lumbar pain similar to the previous two attacks though not so severe. Catheterization and dilatings of the existing urethral stricture proved as effective for relief as previously, and the patient declared herself willing to pursue treatment as advised for prevention of recurrence.

Case 6.—A. F. S., a man, aged 55, entered the hospital, Jan. 28, 1926, complaining of excruciating pain in the left lumbar region that necessitated the giving of scopolamine and other sedatives. Searching examination failed to reveal the kidney stone that was suspected but did disclose the presence of a contraction at the vesical neck that had been the cause of backward pressure and the regurgitation pain from which he had suffered. At least this was our deduction when the patient was almost instantly relieved by the dilatings given, and, with these repeated from time to time, he has never had an attack since that time, five years ago.

Case 7.—J. F. H., a man, aged 37, of Newark, N. J., while traveling west on a train, Sept. 6, 1929, was suddenly attacked with severe pain in the left lumbar region that caused him to "double up in agony," as he expressed it. The attack was accompanied by frequency and difficulty in urination and straining that added to his suffering. He was compelled to leave the train and receive treatment (morphine hypodermics) for two days before he could continue on his way west. On his arrival in St. Louis he consulted me and was sent to the hospital for removal of the suspected stone. He said that two weeks previously he had had a similar attack but not quite so severe. Cystoscopy, catheterization and urography failed to reveal a stone but, on the other hand, gave prompt relief from the pain. With this as a clue, I gave dilatings to a tight posterior urethra, discontinued the use of sedatives and obtained prompt recovery that has lasted to the present time, backed up with occasional dilatings as advised.

Case 8.—A. S., a man, aged 39, of Springfield, Ill., entered the hospital in March, 1928, complaining of acute pain that seemed to begin in the bladder and run upward to both kidneys but was most severe on the right side.

The routine cystoscopic examination failed to reveal evidence of stone but gave relief from the pain, so it was followed by posturethral Kollmann dilatings, and the patient has not had any recurrence since, nearly three years.

Case 9.—R. L. R., a man, aged 34, has been under my care for a year or more, with chronic prostatitis and contracture at the vesical neck, with urinary infection that frequently extends to the upper tract. By various measures the residuum has been reduced from 4 ounces to nothing for most of the time. But attacks of difficult urination occur occasionally, nevertheless.

Nov. 30, 1930, while experiencing a cold day in Chicago, he was suddenly seized with violent pain in the bladder that seemed reflected into both kidneys. He described his suffering as agonizing for the next twenty-four hours, compelling his return home. On arriving in St. Louis he was relieved by catheterization and a good stretching with the Kollmann dilator. While examination for a possible stone or other cause was not overlooked and was, in fact, carried out with negative results, our acquaintance with his condition made it easy to arrive at the diagnosis promptly and to give treatment that brought the desired relief.

In searching for literature analogous to the subject of this paper, I found a contribution by Rénard-Dethy,[12] who refers to renal colic caused by nodules in the prostate or seminal vesicles, and describes three cases of that origin. The patients had finally been relieved by treatments applied to the prostate. His explanation of the relationship was that of reflex nervous influence. He evidently had not encountered the previous contributions of mine, of 1924, 1925 and 1926, for he says: "I have not found publication of a single case of renal colic attributed to a prostatic lesion."

Kartal[13] mentions six cases of renal colic due to seminal vesiculitis (spermatocystitis), observed in the clinic at Zurich.

A contribution that is more nearly analogous to the subject of this paper is that of Dr. C. Lepoutre[14] of Lille, which was made to the Société française d'urologie, Jan. 20, 1930. In his paper, Lepoutre speaks of severe lumbar pain in connection with urination that occurred intermittently for months, in a 65 year old prostatic patient who was finally referred to Dr. Lepoutre for a diagnostic clearing of the mysterious condition prevailing. For eight months the patient had suffered almost daily or nightly attacks of violent pain in the left lumbar region. They occurred either at the time of urination or on feeling the necessity to urinate, especially in case the act was deferred. Roentgenography was negative for calculus. Cystoscopy disclosed an enlarged prostate and a golf-hole ureteral orifice on the left side. The bladder was filled with 200 cc. of collargol suspension, and the first roentgenogram showed nothing in the left ureter or kidney pelvis, but shortly thereafter the patient complained of a strong desire to urinate and immediately of pain in the left kidney. The second roentgenogram, then made, showed the left pelvis and calices well filled; the left ureter was less distended but showed the presence of collargol. Prostatectomy was done, providing easy emptying of the bladder and relief from the colics.

In the discussion that followed this report, sympathetic interest was shown and discussions were given by Marion, Papin, Gayet and Pasteau. The speakers made use of the terms "active reflux" and "passive reflux" to distinguish between regurgitation under pressure through an intact ureteral orifice, and the passive reflux through a golf-hole orifice.

At any rate, there was definite recognition by the speakers present of the condition referred to at this meeting of 1930 and described by me in the previous years noted.

While I appreciate the desirability of direct evidence such as roentgenograms showing regurgitation and overfilled ureters at the time of paroxysms in these cases, it is obvious that such evidence has been unattainable prior to the advent of intravenous urography, because the introduction into the ureter of a catheter would, per se, destroy the evidence that was sought; namely, pent-up urine under backward pressure. But now that intravenous urography is available, it is hoped that that object may be accomplished even though it may entail prolongation of the colic while the investigation is being made. At any rate, it is hoped that the evidence of regurgitation renal colic as a clinical entity herewith submitted may be sufficient to merit the attention of the profession and receive either confirmation or denial from its observations.

ADDENDUM

After hearing this paper read in Philadelphia, Dr. P. E. McCown of Indianapolis kindly submitted the two accompanying roentgenograms of cases illustrating, he believed, the regurgitation that had been the cause of chronic renal pain, in which both were permanently relieved by removal of the obstruction at the vesical neck—one by prostatectomy, the other by dilatings of a urethral stricture which he definitely recognized. Roentgen evidence of ureteral regurgitation is plainly discernible in both negatives, incidental to cystograms made under moderate pressure.

CONSERVATION IN THE TREATMENT OF MOVABLE KIDNEY *

WILLIAM F. BRAASCH, M.D.
ROCHESTER, MINN.

It would hardly seem necessary to reopen for discussion a subject which has been settled and buried several times in the last thirty years; and yet, when it is resurrected with somewhat altered features and set going again with new supporters and followers, it must be dealt with and either allowed to go on its way or reinterred. The gentle art of nephropexy has had such a course in recent years, and it is now enjoying a decided renaissance. Many of the arguments in its favor are not new, and consist of the simple story of palpable nephroptosis, abdominal pain, nephropexy and cure, at least so reported, in from three to six months. The experience of twenty odd years ago, when the operation was widely employed, is surely not forgotten. It will be remembered that many surgeons were most enthusiastic about the merits of nephropexy, and cures were claimed for a great variety of complaints, varying from backache to insanity. When symptoms either similar or referred to other areas, even to the other kidney, reappeared in many cases within a year or more afterward, the operation soon lost its appeal; it was largely discontinued and actually fell into disrepute. In recent years the procedure has been revived by a group of surgeons no less important than the urologists, and its application is now spreading rapidly. The following questions naturally arise: Why has this ancient practice been revived? Has a new or overlooked reason been found, any new method of diagnosis, any recent discovery in pathology or physiology to substantiate it, and, lastly, has a new method of operation been discovered which not alone fixes the kidney permanently but eradicates the symptoms as well?

The present attitude toward the surgical treatment of nephroptosis varies widely. Two extreme views are advanced: that surgical treatment is never indicated, and that most cases of nephroptosis should be treated surgically. The first view is supported by many general surgeons who still remember the unsuccessful results of twenty years ago. The group supporting the latter view includes many urologists who operate promiscuously without regard for other clinical conditions. There is a third group whose members believe that nephropexy is indicated in selected cases only; they differ widely, however, as to the methods of selection and as to the proportion of patients who should be operated on. The more liberal members of the third group would include many cases in which symptoms are referred to the kidney, whether or not any evidence of pyelectasis or of urinary retention is found on urographic examination. They manage to find a considerable number of the patients with nephroptosis who are amenable to nephropexy. The conservative element in this group, however, will insist on definite urographic evidence of obstruction and renal stasis as well as pain referred to the renal area, before advising surgical treatment.

I have long maintained that any surgical or other form of mechanical treatment directed toward the kidney or ureter, without visual evidence of inadequate urinary drainage, is unjustifiable. Any claim that there could be urinary obstruction sufficient to warrant such treatment without evidence of pyelectasis or of ureterectasis has no pathologic or physiologic foundation. I agree with Kidd[1] that there is no indication for the surgical treatment of renal dystopia without such data. Evidence of abnormality in the outline of the renal pelvis, calices or ureter should be demanded before operation is advised. Granted that selection of cases for nephropexy should depend on the results of urographic examination, the problem becomes largely one of urographic interpretation. Such examination will usually show a variable degree of malposition. It is usually advisable to make urograms with the patient in the dorsal and in the erect position, in order to determine the full extent of renal excursion. The degree of renal ptosis has been arbitrarily graded, 1, 2 and 3, the last grade being given when the renal pelvis is at the level of the iliac crest, or lower. The axis of the pelvis and calices is frequently abnormal as the result of renal displacement (figs. 1, 2 and 3).

Renal ptosis, however, even if graded 3, is not an indication for surgical treatment, unless there is evidence also of urinary stasis. Some observers maintain that urinary obstruction might be transient and so slight that it might not cause actual dilatation of the calices, pelves or ureter. Judging from the duration and frequently the constancy of symptoms in most cases, it would be difficult to believe that complete absence of any deformity in the pelvis or ureter would be possible. It is always present with chronic ureteral obstruction from other causes, and why should it not be present with ptosis?

Although gross abnormality in the pelvic outline will be readily recognized in the urogram without a great amount of experience, yet in many cases the interpretation will not be so simple. By gross changes I refer to frank evidence of pyelectasis, as shown by dilated calices and pelvis, usually referred to as hydronephrosis. In most cases in which evidence of abnormality is found in the pelvic outline with nephroptosis, the changes will be slight and characterized by moderate pyelectasis and also, curiously enough, in some cases by evidence of dilatation of the ureter. Whether the moderate degree of pyelectasis noted is always due to actual obstruction is sometimes open to question. Occasionally the urogram will show an outline of the renal pelvis and calices which is not quite normal and still could hardly be described by the term pyelectasis. The outline of the pelvis and calices gives the appearance of being atonic, and the condition has been described as "flabby pelvis." This condition is often

* Read before the Section on Urology at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 12, 1931.

[1] Kidd, Frank: Acquired Renal Dystopia or Movable Kidney, J. Urol. **26**: 327-378 (Sept.) 1931.

in keeping with the condition of the abdominal wall and accompanying visceroptosis. A slight degree of pyelectasis is often found in the course of examination of patients with renal ptosis who have not had lumbar or abdominal pain, so that it is questionable whether this observation should necessarily be regarded as indicative of actual obstruction.

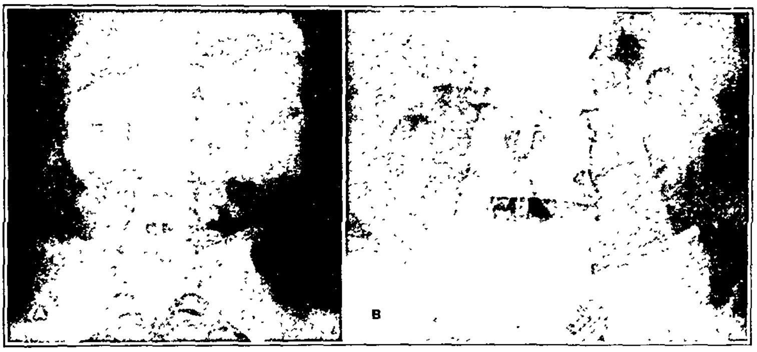

Fig. 1.—*A*, clear visualization of both renal pelves, which are normal, with patient in dorsal position. *B*, with patient in erect position there is evidence of moderate bilateral renal ptosis. There is no evidence of pyelectasis and no visual indication for nephropexy.

Intravenous urography is of distinct value in the recognition of minor degrees of pelvic abnormality resulting from renal ptosis. By comparing the outlines of the two pelves, any difference in size or deformity in the pelves and calices can be readily recognized. Evidence of comparative delay in drainage can also be visualized in the late films. Although urographic examination is invaluable in the selection of cases for operation, I have found that in doubtful cases pyeloscopy, or rather uroscopy, is of great value in the recognition of physiologic abnormalities in the pelvis and ureter. I have been using a 30 per cent solution of iopax (uroselectan) or skiodan, injected through the ureteral catheter, because sodium iodide, formerly employed, often caused irritation and spasm. Roentgenoscopy after intravenous injection has not as yet afforded visualization clear enough for exact interpretation. Uroscopic examination often will give data which can be acquired in no other way, particularly in demonstrating (1) the difference in renal drainage when the patient is in the erect or in the dorsal position; (2) the region of obstruction, if any, and (3) the degree of pelvic and ureteral peristalsis. If there is no evidence of obstruction to drainage, and the peristalsis is normal throughout, there could hardly be any reason for surgical intervention.

The patient's symptoms constitute another significant factor in influencing opinion as to the advisability of nephropexy. If renal ptosis is the cause of renal obstruction it would necessarily be accompanied by intermittent attacks of acute renal pain referred to the affected renal region. It has been common experience, however, that most patients with renal ptosis have variable and often vaguely localized pain. In only a comparatively small percentage of cases of renal ptosis is the pain referred definitely to the region of the kidney. In many the pain is referred to the inguinal, suprapubic or sacral region; or it is diffused over the entire abdomen; or it is shifting, being referred first to one side of the abdomen and then to the other, or it is abdominal at one time and otherwise later. In fact, the subjective symptoms, as one might expect, since psychoneurotic tendencies frequently are observed in cases of nephroptosis, are usually unconvincing. To complicate the situation, cases of nephroptosis are occasionally observed in which lumbar or abdominal pain has never been present and in which urographic examination will disclose mild pyelectasis. Another disquieting feature was noted in several cases in which nephropexy had been done elsewhere with relief of symptoms following operation but in which the kidney was found to be as low and as freely movable as it was before the patient was "cured." Equally confusing is the fact that the degree of renal excursion of the two kidneys may be equal and both pelvic outlines normal, and yet the pain is referred entirely to one side. This problem has been solved by ardent advocates of nephropexy by simultaneous operation on the two kidneys.

If careful clinical examination is ever of therapeutic importance it certainly is in the case of ptosed kidney. When one attempts to determine the cause of abdominal pain, every other organ should be carefully excluded before evidence of renal malposition is looked for. Since renal ptosis is usually evident on casual abdominal palpation, it is frequently regarded as the source of the symptoms, and a thorough clinical examination is not made. A wide variety of lesions was discovered in the course of routine examination of 200 patients who either had been operated on elsewhere for renal ptosis or had been advised to undergo operation. In a review of their clinical records, together with those of 100 patients who were found to have renal ptosis, several interesting observations were made. Most of the symptoms were of a functional nature, which often served to confuse symptomatic evidence of coexisting organic lesions in other organs. In almost all the cases the symptoms could be explained on the basis of evidence of an inferior nervous system, and there was definite clinical evidence of hysteria, psychoneurosis, or constitutional inferiority. In seeking relief from symptoms these patients will grasp at any suggestion of organic lesion and readily submit to surgical treatment. At least one abdominal operation had been performed on almost all the patients, and, on many, three or four

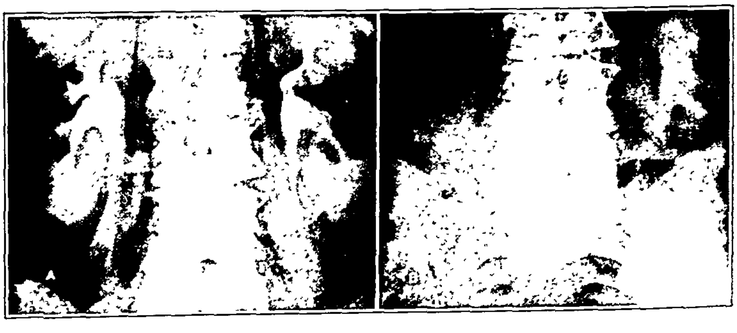

Fig. 2.—*A*, clear visualization of both renal pelves with patient in dorsal position. Bilateral ptosis is graded 1. *B*, with patient in erect position, film made forty-five minutes later shows trace of skiodan remaining in right renal pelvis, which is dimly seen at level of crest of ilium. Left renal pelvis is partially filled and is opposite the fourth lumbar vertebra. Bilateral renal ptosis is graded 3. The absence of complete drainage in forty-five minutes and the absence of pyelectasis would contraindicate surgical procedures.

operations had been performed. Instead of surgical treatment a therapeutic program should have been prescribed, consisting of dietary and occupational suggestions, together with proper exercise, and play or rest, as might be indicated. Correction of posture, massage, and other conservative measures should also be thoroughly tried. Letters from these patients or clinical examinations made a year or more later disclosed that the symptoms of many had been relieved by instructions given them aiming at improvement in their general health. Several were markedly improved as a result of correcting posture. When pain in the back was predominant, removal of foci or use of sacro-iliac belts often gave considerable relief. Only a few of these patients were found later to have intermittent attacks of abdominal pain that could be regarded as amenable to surgical treatment.

Some of the more conservative surgeons who frequently advise nephropexy claim that, if these palliative measures fail to be beneficial, operation is advised even though there is no urographic evidence of renal obstruction. That improvement may be noted in some of these cases within a few months after nephropexy cannot be denied. From a review of the postoperative course of the patients operated on in the clinic for nephroptosis, as well as of patients operated on elsewhere, it was noted that many had been relieved for several months to a year following operation. This might well be explained by several factors: Many patients were undoubtedly improved by the enforced rest, which usually covered a period of several months before they resumed their occupations. In other cases the functional nature of complications and the unbalanced condition of the nervous system were such that the operative procedure itself undoubtedly left a profound therapeutic impression. It is evident that much reliance cannot be placed on the subjective results following operation until several years have elapsed.

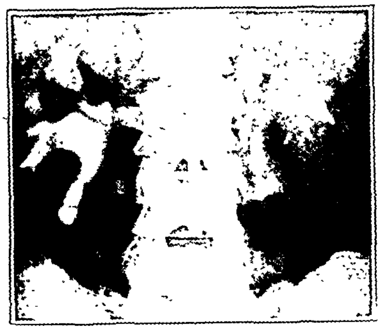

Fig 3.—Bilateral renal ptosis, graded 2 with patient in dorsal position. Evidence of pyelectasis in right kidney. Typical "flabby" pelvis. Uroscopic examination did not show evidence of obstruction to peristalsis in either pelvis or ureter

Spurred on by glowing reports of cures following nephropexy, made by advocates of the operation during recent years, I have made every effort to find patients with renal ptosis for whom nephropexy could be urged with a clear conscience. I have even gone so far in some cases as to waive the necessity of undisputed urographic evidence of stasis. In spite of determined effort, but few patients have been found on whom the operation was justifiable. Either the patient had a hopelessly psychoneurotic disposition and the symptoms were of a doubtful nature, or there was clinical evidence of some other abdominal lesion, or the pyelographic evidence was negative. In fact, it may be stated that unless there is visual evidence of renal obstruction in the effort to correct definite abdominal symptoms, it would usually be advisable to explore the abdomen before attempting nephropexy.

Having demonstrated the existence of renal stasis, the next question which arises is whether renal ptosis is the cause of the patient's symptoms. It is doubtful whether renal ptosis alone could cause urinary obstruction. In other words, there must be some other factor actually causing ureteral obstruction which developed as a result of ptosis, such as fixation of the upper part of the ureter by bands of tissue, adhesions, the results of periureteritis, or anomalous blood vessels. It may be difficult to determine, on surgical exploration, to what extent renal ptosis is an etiologic factor. Evidence of obstruction in the upper part of the ureter may be apparent, but it may be difficult to determine whether coexistent ptosis is etiologic or coincident. Nephropexy was often employed as a precautionary measure in addition to other procedures in a series of plastic operations for hydronephrosis, although in many cases it seemed doubtful whether ptosis was much of a factor in causing pyelectasis.

It is difficult to form any definite opinion as to the value of the different types of operative technic advanced by various surgeons. One could easily be in doubt as to the best method of renal fixation, because of the many methods that have already been advanced. In fact, almost every surgeon who had performed a number of these operations has his own pet technic; usually the technic embodies the suggestions made by Albarran,[2] Edebohls,[3] and others. It is common knowledge that in most cases in which the kidney has been operated on, secondary exploration will show that the kidney is firmly fixed by scar tissue, and secondary mobilization is quite difficult. On the other hand, I have observed patients who claimed that renal fixation had been made elsewhere, and the kidney was just as mobile as it was supposed to have been before operation. It is evident, therefore, that when nephropexy has been done it is important to make urographic studies after operation in order to determine the results accomplished.

The following conclusions would seem logical:

1. Renal ptosis without urinary obstruction has no clinical significance and is seldom, if ever, the cause of symptoms.
2. Renal obstruction as the result of ptosis can always be demonstrated by urographic or uroscopic examination, and operation is justifiable only in the presence of such evidence.
3. In the majority of cases in which nephropexy has been done without previous demonstration of evidence of urinary stasis, the symptoms will return within one or two years following operation.
4. Postoperative urographic examination is necessary to determine the permanence of normal renal position as well as improvement in drainage.
5. The percentage of patients having nephroptosis who can be relieved of their symptoms by renal fixation will be comparatively small.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. JECK, LEWIS AND BRAASCH

Dr. W. Hersey Thomas, Philadelphia: Dr. Jeck's paper shows a greater incidence of horseshoe kidney than any other series with which I am familiar except that reported by Naumann in 1897, who found 1 case in 600 autopsies. It should be noted that the preoperative diagnosis was made in 50 per cent of the operations at Bellevue. In the 108 cases collected from the literature and carefully studied by Rathbun in 1924, only 22 per cent had been diagnosed prior to operation. Our

3. Edebohls, G. M.: The Surgical Treatment of Bright's Disease, New York, F. F. Lisiecki, 1904

greatest aid in diagnosis unquestionably is urography. Dr. W. Edward Chamberlain recently called my attention to the fact that, when the calices point in an opposite direction from the normal, a horseshoe kidney is always present. It has also been pointed out that in horseshoe kidney there is an interruption of the outlines of the psoas muscles. Just what is to be done in any given case will always challenge the best judgment of the operator, but his decision will be largely determined by the amount of his preoperative study of the case. The paper by Dr. Lewis reaffirms his former writings and furnishes fresh evidence of the soundness of his views. "Stone colic without stone" as a diagnosis has frequently resulted in numerous painstaking and destructive searches for something that was not present. Dr. Lewis has offered in the way of diagnosis something that is distinctly better. Only too frequently in the past have patients been discharged with a diagnosis of urolithiasis, in the belief that in some mysterious way the calculus has passed and escaped detection. May I suggest that the shortening of the intravesical ureter in Gruber's experiments is analogous to that seen in an oblique inguinal hernia in which there is a constant tendency toward the development of a direct from an oblique canal by the approximation of the internal and external rings. Intravenous urography, with its great possibilities for demonstrating the physiology of the urinary system as a whole, should do much to establish further the existence of regurgitation renal colic, and I am sure that in future cases of this type the possibility of its occurrence will not be ignored. Dr. Braasch's end-results in several hundred patients operated on from two to twenty years ago impresses on all of us the importance of selecting the proper cases of nephroptosis for fixation. For many years my own indications for operation have been limited to two—urinary obstruction and the occurrence of a complicating infection. It is readily seen why the indiscriminate fixation during the earlier days of renal surgery brought operations for nephroptosis into deserved disrepute.

Dr. Henry Sangree, Philadelphia: I wish to refer to some of the work of the late Dr. Thomas, who had collected a number of these cases. One case was in a girl, aged 8, who had considerable pain, and in the erect position the kidney could be seen descending to the second vertebra. The child was underweight, and a pediatrician took care of her in an effort to build her up and get some fat to hold the kidney in better position. Some credit must be given to him. A roentgenogram taken after three months showed some improvement, but there was still a hydronephrotic cap. In the erect position the kidney was held in the normal position by means of a belt, and the child was relieved of symptoms. My associates and I use a belt to fit these children, and it is put on in the Trendelenburg position, holding both kidneys up in good position. We have obtained excellent results in the conservative treatment of these patients by holding the kidney up and getting rid of the hydronephrosis due to the kinking of the ureter.

Dr. Robert Gutierrez, New York: Two types of cases of horseshoe kidney must be considered clinically. There are those cases in which pathologic changes have been established or in which concomitant lesions are present, as in the cases which Dr. Jeck described. The second group is formed by persons with horseshoe kidney in which no associated pathologic changes or visualized lesions are present, although the patients are suffering from unrecognized symptoms which constitute the horseshoe kidney syndrome. This syndrome has been present almost uniformly in the series of cases I had the opportunity to study, with an incidence of about 96 per cent. The horseshoe kidney syndrome is characterized by pain in the epigastrium or in the umbilical region, radiating to the lumbar region and accompanied by the chronic constipation and urinary disturbances for which patients come for examination. I have come to the conclusion that, owing to the prominent position the horseshoe kidney occupies in the middle of the abdomen (lying on the aorta, vena cava, the solar plexus and the sympathetic and parasympathetic nerves), the weight, the pressure and the incarceration of the organ are the paramount etiologic factors in the associated pathologic changes and the horseshoe kidney syndrome; and that these conditions are due also to the anterior position of the pelves and ureters, for they lie in front of the renal mass, which obviously interferes with their normal dynamic and physiologic function, producing lack of drainage and urinary stasis. In view of these factors I am firmly convinced that not until the isthmus of the horseshoe kidney is divided by a symphysiotomy procedure can permanent cure be obtained. The urographic data in the diagnosis are essential and are well known since Braasch pointed them out. However, in this connection, in studying the films of this series of cases that we have diagnosed, I have found a new sign which I think is of pathognomonic value in establishing an accurate diagnosis, particularly in these days when intravenous pyelography is coming into extensive use. I have called this new sign the horseshoe kidney triangle. It is formed by drawing a triangle in the bilateral pyelogram, uniting the two lower innermost calices and drawing a line from each of these to the point where the bisiliac line crosses the midline, which point becomes the apex of the triangle. In horseshoe kidney this basal triangle is about 20 degrees, while in normally placed kidneys the average is about 90 degrees. After measuring a series of more than 100 bilateral pyelograms in which the kidneys are normally placed in the lumbar fossae, I have found this lower basal angle to be almost always more than 90 degrees in normally placed kidneys, while in horseshoe kidneys, owing to the approximation of the innermost calices of the two sides, this angle is extremely narrow, with an average of about 20 degrees. I think, therefore, that this is a very graphic and valuable sign to assist in establishing a correct diagnosis of the condition.

Dr. N. G. Alcock, Iowa City: I have found an interesting curiosity in a horseshoe kidney. The patient was a large man who had had hematuria on two or three different occasions. He fell on his elbow, on the right side, and a big tumor developed in the kidney. I found that he had two orifices on the right and one on the left, and in introducing the catheter we found an opening up under the tenth rib which showed that a double kidney was present. The psoas muscle did not show. In the subsequent pictures we could see the two pelves. It has been said that in horseshoe kidney the calices point in and not out, but in the six cases we have seen they have pointed outward. In this case cystoscopy was done, a large catheter was put in, and sodium iodide was introduced. The pyelogram revealed an enormous hydronephrosis of the one kidney. When the kidney was exposed it looked like an enormous polycystic kidney, but I broke one of the apparent cysts and the kidney emptied. The isthmus was cut across after being clamped and the patient was all right except that drainage continued for fifteen or sixteen days before any urine passed.

Dr. William E. Stevens, San Francisco: Morris reported 19 cases of horseshoe kidney which he had found in a series of 18,244 recorded autopsies. Most of my patients have complained of a sensation of pressure or pain in the abdomen, which has been increased by exercise and relieved by rest in bed. I have occasionally been able to palpate an oval mass in the abdomen. One of my patients complained of symptoms suggestive of pelvic inflammatory disease. At operation a horseshoe kidney was found, in addition to a large cystic ovary and an appendix which showed evidence of previous inflammation. A third pelvis and ureter arose from the isthmus of this kidney. No similar case has been recorded in the literature. Another of my cases was of interest because of the fact that a diagnosis of horseshoe kidney was justifiable without pyelography, because of the approximation of the lower poles of the two segments. The plates of a third case are interesting because of the fact that both segments of the horseshoe kidney are seen to be located to one side of the vertebral column, and one of the segments is ectopic. Many patients with horseshoe kidney never have symptoms. This condition will be discovered more frequently with the increasing use of intravenous pyelography.

Dr. Hermon C. Bumpus, Jr., Rochester, Minn.: Some years ago, in trying to ascertain the mechanism of renal back pressure in patients with prostatic obstruction, I discovered that regurgitation occurred in 4 per cent of the cases. In none of these cases, however, was there a history of any clinical entity such as Dr. Lewis describes. I believe that the colic is a result not of regurgitation but of peristalsis in a normal ureter trying to overcome some obstruction in the intramural portion of the ureter. Dr. Lewis spoke of intravenous urography making possible for the first time visual demonstration of these cases.

It would demonstrate ureteral retention as the result of obstruction but I should think it would interfere with the demonstration of mediums going from the bladder up the ureter.

Dr. Edward L. Merritt, Fall River, Mass.: Dr. Braasch has spoken of the need of finding renal stasis before one can definitely blame the kidney for the symptoms. I think this is true, just as it is now believed that renal back pressure must be demonstrated before one can blame ureteral stricture for symptoms. The point I wish to bring out is that I believe these pyelograms should be made with the patient erect, in order that one may find the kidney in its normal position. If ptosis is present, this method will demonstrate it much better than with the patient lying down. I think that the use of a belt should be considered, and believe that it will give relief in cases in which operation is contraindicated. Last year I had two cases in which there was definite nephroptosis in the remaining kidney, one kidney having been previously removed. In these cases a kidney belt was applied, always being put on by the patient while lying in the Trendelenburg position. This gave absolute relief to these patients. I should like to have Dr. Braasch tell how he feels about the use of belts.

Dr. George R. Livermore, Memphis, Tenn.: In a case of movable or ptosed horseshoe kidney with hydronephrosis, marked pain and dysuria, at operation the kidney was movable an inch or more; a nephropexy was done, with entire relief from symptoms. I think we are indebted to Dr. Braasch for so lucidly explaining this subject and giving us his views as to when to operate. We all know that nephropexy is not 100 per cent effective, as shown by cases in which operation was performed at the Mayo Clinic and elsewhere. I have recently had a case in which the kidney slipped after being operated on by the Kelly method, and the patient has a return of symptoms. It is remarkable what relief a large percentage of patients obtain from a well fitting corset.

Dr. William P. Herbst, Minneapolis: Any problem that is so controversial as the indication for nephropexy in painful ptosed kidneys, with equally able men taking opposite sides, must have some explanation. As a partial explanation I wish to submit that those who champion the cause for nephropexy because of their good results unwittingly do a renal sympathectomy of variable degree and that those who are against nephropexy because of unsatisfactory results do not disturb the renal plexus in their nephropexy technic. The operation of nephropexy, as done at the Mayo Clinic, consists of mobilization of the kidney to an extent which allows the kidney to be fixed in what is considered the normal position without even visualizing the renal pedicle and consequently without disturbing the renal plexus. The operation of nephropexy, as done by Dr. Foley of St. Paul, who is one of the most enthusiastic advocates of nephropexy, consists of a very beautiful exposure of the kidney, renal pedicle and upper ureter which cannot help but result in considerable disturbance of the renal nerve supply. In addition to the foregoing observations, I wish to call attention to the work of Dr. Elmer Hess of Erie, who has done a number of sympathectomies in cases of painful renal ptosis without employing any method of fixation except postoperative abdominal pressure and position. His results with this type of procedure have been as satisfactory as any nephropexy. I have two pyelograms—before and after a nephropexy. The first one does not demonstrate any abnormality except a slight ptosis. The second one, done after a nephropexy, demonstrates a kidney rotated on its horizontal axis with an acute angulation of the ureteropelvic junction, so that anatomically it is worse than before operation, yet the patient has had complete relief for over a year and a half. I believe that the operation in this case was successful because the operator destroyed enough of the renal plexus in his mobilization. In view of the fact that in abnormally mobile kidneys as many are symptomless as are pain producing, I wish to suggest that the pain in cases of abnormally mobile kidneys is frequently due to abnormal motility syndromes of a spastic nature due to disturbed sympathetic nerve control involving the individual calices, ureteropelvic junction or ureter, as described by the Harrises of Australia, recognizable only by pyeloscopy and controllable by various drugs or renal sympathectomy.

Dr. William F. Braasch, Rochester, Minn.: There is no doubt that nephropexy is indicated in selected cases with renal ptosis, but I do not think that we are agreed as to just what should be regarded as an indication for surgical treatment. I am certain that evidence of renal obstruction is a definite indication and usually the only one. I did not have time to go into conservative treatment, but it seems evident that in many cases the treatment is similar to that employed with psychoneuroses. Many patients with renal ptosis have definite evidence of psychoneurosis and it is usually not secondary to renal dystopia. Another important feature in the conservative treatment of these cases is the correction of posture. Many of the patients will be found to have some deforming sacro-iliac disease, and in these cases the wearing of a proper belt has been of great importance in relieving the symptoms. In a series of fifty cases in which a diagnosis of renal ptosis was made and conservative treatment was advised rather than operation, we reviewed the results two years later. Many of the patients were markedly improved following rest, massage, diet, increase in weight, and so on. Conservative treatment should always be given these patients before one advises nephropexy. It is probably true that, owing to prejudice against operation for renal ptosis there are occasional patients who are suffering needlessly and who might be relieved by nephropexy, as Dr. Lewis maintains. However, there is a far greater number who are now being operated on for renal dystopia in whom operation is not indicated and who would be much better off with conservative treatment.

Dr. Bransford Lewis, St. Louis: Most members of the profession say, "Do not speak of anchoring a kidney; we are not doing that any more." I think this cannot be decided on any such generalities. Statistics will not tell whether or not to operate on a given patient. One must determine that by the conditions found in each case. Dr. Braasch is conservative, but his is not the blind, harmful conservatism of the general profession. Urologists have to educate the profession to a reasonable, logical conception of this subject, which has its place just as much as any other endeavor in medicine or in surgery. With regard to the other type of conservatism, recently Kidd read a paper on this subject and said that before he operated on such a patient he had her wear a belt for six months. Lowsley has said that women should wear a belt for a year before operation. Would these gentlemen defer other needed operations for so long a time? A few weeks of wearing an abdominal belt as a therapeutic test is sufficient.

Dr. A. I. Folsom, Dallas, Texas: The question raised by Dr. Lewis is interesting. I have never seen a case that attracted my attention as coming in the category he described. I have seen cases due to inflammatory processes in the vesical neck. My explanation was that the inflammation had produced a reflex spasm at the vesical neck, which produced a reflex spasm of the ureteral outlet and caused the colic, instead of the regurgitation causing it. Whether it is regurgitation or spasm will have to be thoroughly studied. In regard to fixing floating kidneys, there is too wide a divergence of views after so many years. I think that many more floating kidneys cause symptoms than Dr. Braasch brought out, and there are many that produce distressing symptoms, and the man who does not attempt to pick out these cases is failing in his duty. I have no better results and no more grateful patients than in nephropexy. I think Dr. Braasch is wrong in stating that there must be definite evidence to show that the kidney pelvis is dilated. Before I submit a patient to nephropexy, that patient must have a definitely located pain in the loin, and it must be definitely aggravated in the erect position. I admit that there is an occasional rare case in which this is reversed. I had one such case and I watched that patient for a long time before I operated, but I got a brilliant result. I think that in 99 per cent of the cases the pain must be aggravated on standing and must also be relieved by the patient lying down. In addition to that, I require another standard, which is that the distention of the kidney pelvis must reproduce the pain the patient complains of, and she must identify it without any help from me. I believe that if one limits one's operation to those cases in which there is definite pain located definitely in the loin, which is unquestionably aggravated by standing and relieved by lying down and which is definitely reproduced by filling the kidney pelvis, one will be the most enthusiastic supporter of nephropexy in these cases, in which it undoubtedly is indicated.

Dr. Howard S. Jeck, New York: Dr. Gutierrez mentioned a symptom complex which he ascribes to horseshoe kidney. Essentially he has reference to Rovsing's sign; namely, suprapubic pain which is relieved when the patient lies down. Of interest in this connection is a case in which the patient was operated on by my associate, Dr. Keyes. For years this patient had abdominal discomfort. At times she also had sudden attacks of pain in the right side and experienced increasing inability to exercise because of the abdominal pain thus produced. A diagnosis of horseshoe kidney was made by a pyelogram. Division of the isthmus, together with raising the right half of the kidney about 4 cm. and anchoring it, afforded complete relief. Dr. Alcock said that almost all the cases he has seen of horseshoe kidney show the calices in the pyelograms pointing outward. This is true in a number of instances, but in most of them the calices point inward. When this occurs, I believe it should always arouse one's suspicion of the presence of horseshoe kidney and when the calices point outward other factors will have to be taken into consideration in order to make a diagnosis. In the cases Dr. Stevens has just described and demonstrated, I think that most of the calices pointed inward.

Dr. Bransford Lewis, St. Louis: In answer to the suggestion of Dr. Bumpus that this is peristaltic pressure against the ureteral orifices, that is theoretical and he has not proved it any more than I have proved my belief. He has proved the possibility and relative frequency of regurgitation. If these patients are crying with pain for twenty-four or forty-eight hours and have been having recurring attacks for ten or fifteen years, and if one puts in a catheter and relieves the retention, the patient at once feels better, without anything having been done to the ureteral orifice. Relief of obstruction at the vesical neck alleviates the pain, and for as long as the obstruction is relieved.

RETROBULBAR NEURITIS DUE TO THALLIUM POISONING FROM DEPILATORY CREAM

REPORT OF THREE CASES *

WILLIAM MAHONEY, M.D.
BOSTON

Within the last two years, thallium has been incorporated in a widely advertised depilatory from which many serious consequences have been noted. Its damaging effect on the optic nerves will be the primary concern of this communication.

While looking for tellurium in a flue-dust of roasted seliniferous pyrites in March, 1861, Sir William Crookes[1] observed a green line in the spectroscope which led him, after further study, to announce the newly discovered element thallium, descriptively named from the Greek θαλλός, or Latin *thallus*, a budding twig, a word which is frequently employed to express the beautiful green tint of young vegetation.[2] This new element was presumed to belong to the sulphur group until the following year.[3]

Its metallic nature was demonstrated by Lamy of Lille in 1862, when he isolated[4] it and described its properties. During his studies he experienced weakness and pains in the legs which made him suspicious of a toxic influence from the metal. This he demonstrated experimentally by giving animals thallium sulphate and producing intestinal and respiratory embarrassment with peripheral paralyses and general weakness.[5]

Many others noted its various properties, so that it was soon used therapeutically with effect in treating colitis and the night sweats of tuberculosis. From these uses its present favor accidentally originated, for in February, 1898, Combemale[6] reported loss of hair in tuberculous patients whose night sweats he was controlling with thallium acetate. Huchard,[7] Jeanselme[8] and Guinard[9] made similar observations, and Hallopeau[10] at this time suggested its use locally for hypertrichosis, beginning his experimental work on guinea-pigs. The animals died within forty-eight hours after the local application of 50 per cent thallium ointment without effect on the hair, and he suggested a less potent dosage.

Sabouraud[11] is often credited with the use of thallium acetate purposely to produce alopecia. In 1912 he reported his experiences as follows: There was referred to him in 1897, because of baldness, a woman who had had diarrhea for which thallium acetate had been prescribed, with resulting relief of the intestinal disturbance. Within two weeks her hair fell out and it began to grow again after six weeks. This he felt might be a wise way to treat ringworm of the scalp, producing a temporary alopecia by local and internal thallium administration; but, although it was effective in the way desired, there were toxic results, namely, albuminuria, subcutaneous ecchymoses, sialorrhea and tachycardia. Because of this, Sabouraud came ultimately to prefer roentgenologically produced alopecia to that chemically produced. However, he had for five or six years before his report (1912) used mild (1 per cent) local applications in managing hypertrichosis. He cautioned against the dangers from too powerful and too large doses but observed no signs of intoxication even after eighteen months of daily use as advised.

The pharmacology of thallium has been studied by Dixon[12] and his observations are these: Although it is very closely related to lead as an element, immediate colic is not produced by injection, but rather a latent effect of the same type. The first response is a relaxation of the smooth muscle of the bronchioles, intestine and uterus. It acts on the autonomic nervous system as does strychnine on the central nervous system, allowing impulses to pass more readily than normally. So he believes that the alopecia is produced through the autonomic nervous system and supports his views by the observations of others who state that the hair of the head is under the trophic control of the internal secretory system through the sympathetic nervous system. He maintains that there is no local effect on the skin or blood vessels and that only after absorption is the hair affected. Experimental work demonstrated not only a depilatory effect but also a stimulatory influence on hair, for, after a group of animals had been shaved, those receiving thallium were covered sooner and with a heavier coat than litter controls.

Roentgen depilation was in fávor in treating ringworm at the beginning of the war, and countries such as Mexico and Russia, which were unable to import the apparatus for irradiation, were forced to the development of another safe method. Thus Cicero[13] with Peter,[14] in Mexico City, followed Sabouraud's earlier work and developed the use of thallium acetate so that it was effective without toxic influence. So also did Buschke in Berlin, whose extensive earlier experimental work on alopecia[15] as well as his more recent pharmocologic studies[16] helped in the development of thallium therapy against the tinea.

In the commercial field, thallium has been used in Zeliopaste as a rat poison and in Koremlu Cream as a depilatory. Again toxic effects have cropped out, even as they did when it was prescribed therapeutically, and the literature has included untoward experiences even from the days of the isolation of thallium to the present-day difficulties in vision seen after the use of a proprietary depilatory.

Lamy in 1862 reported his experience while working with the metal, namely, weakness and pain in the legs, although Crookes is said to have at this time taken several grains without noting any ill effects. Richet[17] in 1899 observed muscular atroph [illegible] ge to the central nervous system by [illegible][18] in 1902 had a patient, a physician, who took thallium sulphate and experienced paresthesia of the fingers and toes with pains in the legs, abdomen and perineum, tenderness over the nerve trunks, and partial paralysis of the lower extremities. There was later a total loss of hair and recovery from neuritic symptoms. In 1909 Cicero[19] spoke of the dangers from its use in depilation for tinea, and in 1912 Sabouraud[11] mentioned his experiences of excessive salivation, tachycardia, albuminuria and ecchymosis.

More recently, symptoms of various kinds have been reported from therapeutic, accidental or malicious administration. Most isolated reports have been of adults, in whom the margin of safety is much smaller than in children (Sluyters[20]). But several mass misfortunes have occurred in which dosage was miscalculated in the clinical treatment of tinea of the scalp in children (Lynch and Scovell,[21] and Merkel[22]). The syndrome has often been very puzzling, even acute abdominal symptoms being simulated, as Ramond[23] reported. Rubenstein[24] has observed encephalitic-like phenomena. There have been many reports of polyneuritis (Short,[25] Waring[26]), and some with psychic manifestations and kidney involvements (Deutsch,[27] Heinichen[28]). Retrobulbar neuritis was noted by Kaps[29] in a patient who became demented before death, and suicidal attempts have occurred.[30]

Toxic optic neuritides are due to many causes and the possible attribution to a cosmetic so little concerned us in the first of our three patients that suspicion was not aroused until the second one had been seen a month later; whereupon inquiry disclosed the probable cause of the first patient's trouble.

These patients were referred to the neurosurgical service of the Peter Bent Brigham Hospital by ophthalmologists because of failing vision and suspected chiasmal mischief.

Case 1.—*Peripheral neuritis. Falling hair. Failing vision. Nervousness. Central scotomas. Retrobulbar neuritis. Ventriculography with normal results. Discharged unchanged. History of use of Koremlu Cream subsequently elicited. Improvement of vision after discontinuance of cream.*

Miss L. L., an Italian domestic of 29, was referred by Dr. W. N. Hughes of Providence because of suspected suprasellar tumor. She complained of failing vision for fourteen months, noted especially in the central part of her visual field. Lenses were fitted without improvement and for seven months she had been unable to read. Her trouble progressed so that she could not cross the street without assistance. One year before entry she had had pains in the ankles and legs which interfered markedly with her walking but which latterly had worn away and the diagnoses made were "fallen arches" and "arthritis." In retrospect, her past history contained the clue to her predicament. She had had for five years a bothersome facial hirsuties which she had been more recently removing with a proprietary cream the name of which was not known and the importance of which at this time was overlooked.

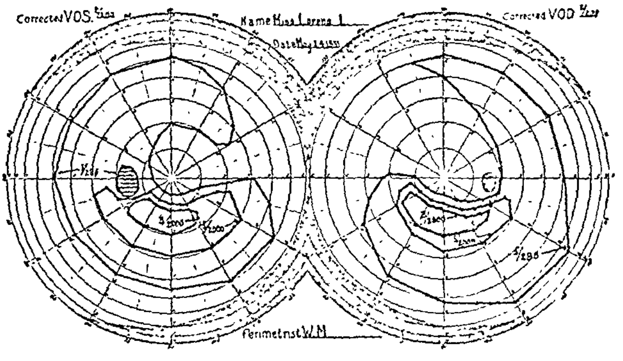

Fig. 1.—Visual fields in case 1.

On examination, hypertrichosis was marked. Her visual acuity was 3/200 and visual fields demonstrated large central scotomas with bilateral upper nasal quadrantic defects (fig. 1). It was not easy to determine whether the atrophy was primary or secondary, but it was thought that she had a retrobulbar neuritis. Intra-ocular tension was 17 mm. The sella was normal by roentgen examination and all laboratory studies were within normal limits. No focus of infection could be found. An ophthalmologic consultant so favored a secondary optic atrophy that on his suggestion further efforts were made to rule out the possibility of long-standing intracranial pressure, whereupon a ventriculogram disclosed normal ventricles and she was discharged, the cause of her trouble really unknown, with the advice to prepare to learn braille.

After the second patient was seen, further inquiry revealed that the proprietary depilatory used was Koremlu Cream, which she had applied daily to her face, arms and legs for a year and a half. She was advised to discontinue this and six months

following she has reported improvement, so definite, in fact, that she is now able to write the letters describing her progress and is preparing to return to work.

Case 2.—*Failing vision. Peripheral neuritis. Central scotomas. Retrobulbar neuritis. Loss of hair. History of use of Koremlu Cream. Improvement after discontinuance of the depilatory.*

Mrs. B. De G., aged 28, a graduate nurse, was referred here by Dr. L. P. Jackman of Glen Cove, N. Y., because of suspected intracranial neoplasm. She complained of blurring of vision for three months, which progressed to such an extent that for the month and a half before entry she was unable to read or to write. She had also noted failure of central vision. For two months she had had very severe pains in her feet and legs which were said to have been due to "fallen arches," "contracted arches" and to "arthritis." During the last months handfuls of hair fell out whenever it was shampooed. She had been using Koremlu Cream for fourteen months with daily applications to the face.

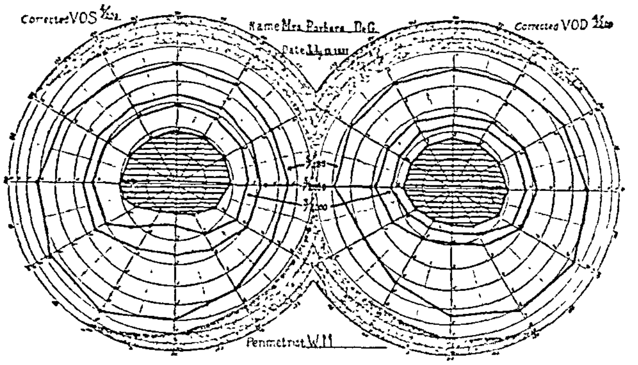

Fig. 2.—Visual fields in case 2.

Examination revealed a visual acuity of 4/200 with marked central scotomas (fig. 2), and a retrobulbar neuritis was noted on inspection of the fundi. The sella was normal by roentgen examination, and laboratory studies were all within limits.

She, too, was advised to discontinue the cream. The pain in her legs disappeared one month after discharge and her visual acuity has improved from 4/200 to 20/70.

Case 3.—*Use of Koremlu Cream. Peripheral neuritis. Failing vision. Nervousness. Falling hair. Low visual acuity with central scotomas. Retrobulbar neuritis. Bilateral motor and sensory involvement of legs.*

Mrs. E. G., aged 35, a Jewish housewife, was referred by Dr. H. E. Davis of Portland, Maine, because of loss of vision and weakness of the lower extremities. For fifteen months she had applied Koremlu Cream to her upper lip and chin nightly. For five months she had pains in the feet and legs and experienced difficulty in walking, which was said to have been due to "fallen arches," to "sciatica" and to "neuritis." With this there was associated weakness of the legs which caused her to be confined to bed until three weeks before entry. Because of the discomfort in her feet she had overlooked her failure of vision, which had existed for probably four months and was so extensive that for three and a half months she had been unable to recognize people. During this time she was also very easily upset emotionally and was especially nervous.

On examination it was found that she had a visual acuity of 3/100, and visual fields showed large central scotomas (fig. 3). There was definite retrobulbar neuritis. Weakness was marked in both legs, with hypotonicity and hypo-active knee and ankle jerks. There was hypesthesia over both legs and tenderness over the calf muscles. Gait was markedly impaired by the weakness as well as by a definite ataxic element. Roentgen and laboratory studies were entirely within normal limits.

Each of these patients gave a history of use of this proprietary depilatory, Koremlu Cream, which has long since been brought to the attention of the Bureau of Investigation of the American Medical Association, and on which the bureau reported[31] with regard to its constituents, all this because of the appearance of peripheral neuritides in people who had been using this cream. The review indicated that the active principle was thallium and the percentage of the acetate present was 7.18, an unusually bold potency in view of Sabouraud's earlier caution to use it so sparingly and in a strength no greater than 1 per cent. In presenting the proprietary cream, the distributors advertise it most attractively, convincingly, and with absolute assurance that no harm will follow its use.

Our concern in this matter has been primarily with the most distressing effect on the nervus opticus. Careful combing of the literature has bared these observations. Richet[32] in 1899, after experimental work, reported that thallium as well as lead produced a noninflammatory keratitis characterized by progressive opacity of the cornea. In 1927 Kaps[29] told of a situation wherein a rat poison containing thallium was given with malicious intent. Typical difficulties followed in the nature of alopecia, peripheral neuritides, with, in addition, failure of vision and retrobulbar neuritis, before dementia and death. In 1928 Buschke[33] and his co-workers reported the experimental production of partial optic atrophy in animals, which they considered to be a new feature. In May of this year Duncan and Crosby[34] from the Cleveland Clinic, in reporting a case of thallium poisoning following the use of Koremlu Cream, spoke of its likeness to lead poisoning because of the cramplike abdominal pains with peripheral neuritis, and casual mention was made that "at times vision was blurred" but ophthalmoscopic examination demonstrated nothing unusual.

SUMMARY

My purpose in this paper is to point out the dangers that follow long-continued use of a preparation containing a liberal percentage of thallium. The three examples presented were patients who entered a neurosurgical clinic as "intracranial tumor suspects" and were found to have an advancing retrobulbar neuritis. Their failing vision has been checked and improved by discontinuing the employment of what, therefore, is the most probable source of the disorder.

INFERTILITY AND STERILITY

AN ANALYTIC STUDY OF THREE HUNDRED COUPLES *

IRVING F. STEIN, M.D.
AND
MICHAEL L. LEVENTHAL, M.D.
CHICAGO

The treatment of sterility has undergone a complete revision in the past decade, chiefly because of the contributions of American gynecologists. This interest was stimulated mainly by the fundamental work of Rubin,[1] Hühner,[2] Reynolds and Macomber,[3] Evans,[4] and Cary.[5] The notable publications of Dickinson,[6] Forsdike,[7] Meaker,[8] Anspach [9] and many others have added greatly to the study of the subject by emphasizing the need for an orderly and complete investigation of the couple rather than of the individual. These authors have shown the value of recording complete case histories and the importance of correlating published reports. Meaker's classification has been widely accepted as a standard for the investigation of the sterile couple and his plan of group study, so successfully put into operation in Boston, is deserving of universal commendation and adoption.

Empiric procedures, such as dilation and curettage, the use of the intra-uterine stem, amputation of the cervix, plastic operations on the cervix, and various uterine suspension operations, have been replaced by the more logical and simple investigative tests, such as Hühner's and Rubin's, and by conservative cautery treatment of the damaged cervix.

MODE OF INVESTIGATION

In the past seven years we have examined and studied 300 couples who came to us because of childlessness. Most of these patients were seen in private practice, and a minority of them were observed in the gynecologic department of Mandel Clinic of the Michael Reese Hospital. In making our investigation we adopted the general plan of Meaker (table 1), having modified it somewhat, and amplified it by the addition of diagnostic pneumoperitoneum and the combined use of utero-salpingography (iodized oil) and pneumoperitoneum. We wish to emphasize the importance of the sequence in which the diagnostic tests are applied in the study of the sterile couple, and also the needlessness of proceeding to completion of the investigation when a definite and final etiologic factor is discovered. For instance, when an aspermia is found on Hühner's and on condom examination, it is unnecessary to proceed to the patency test for the diagnosis of sterility. However, much may be learned, especially in reference to the multiplicity of etiologic factors, if the entire investigation is carried out.

    - (*a*) Basal metabolic rate

In the management of our patients the performance of the routine diagnostic procedures here outlined was interrupted at any point when examination revealed a definite cause for sterility in the mating. If on the initial gynecologic examination such a pathologic condition was discovered, further tests were postponed pending successful removal of the cause. Furthermore, when the postcoital examination was made and a definite male factor was discovered to account for sterility in the mating, patency tests were not required and usually were not performed. Therefore for purposes of analysis and study of the material we have divided our cases into two groups; namely, those subjected to complete investigation and those subjected to incomplete investigation. Although all couples were investigated to the point of a definite diagnosis, only 175, or 58.3 per cent, required the complete investigation here outlined.

[9] Anspach, B. M.: Am. J. Obst. & Gynec. **19**: 1 (Jan.) 1930.

We have varied somewhat from the usual classification of sterility and infertility, as we have not considered time alone as a cause for sterility. The couples whom we found on investigation to possess the necessary requisites of fertility (Meaker) but who nevertheless did not reproduce we classed as infertile rather than as sterile, regardless of the number of years of marriage. Primary infertility or sterility included those patients in whom no pregnancy had occurred either in the present or in a previous mating, and secondary infertility or sterility included those in whom conception had occurred one or more times in the mating of either partner or of both together. Fifty-seven (19 per cent) of the 300 matings were classed as infertile, as a result of a complete investigation. Forty-seven showed primary and ten secondary infertility. Of the 243 sterile couples, 125 required incomplete investigation to establish the diagnosis. There were 181 cases, or 74.5 per cent, diagnosed as primary, and 62, or 25.5 per cent, as secondary sterility. We found female factors in 217 (89.4 per cent) of the couples, male factors in 70 (28.8 per cent) and both male and female factors in 44 (18.1 per cent) of the 243 couples in which sterility was diagnosed. Had we adopted the usual three year criterion for childless marriage (or 2½ years, Polak [10]) we would have shown a larger percentage in the sterility group.

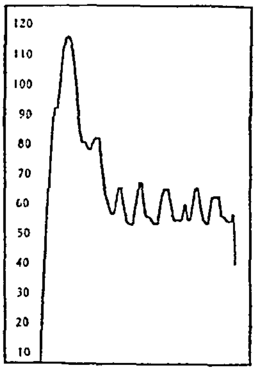

Fig. 1.—Kymographic tracing: patent fallopian tubes.

There is no good reason for postponing a sterility investigation in a couple desiring offspring, even though they may have been married only a short time. For in the course of such an early investigation some obvious cause of sterility may be discovered which on removal may be promptly followed by pregnancy.

FEMALE CAUSES OF STERILITY

In listing the causes of sterility from our charts, we observed that the usually recognized female causes are outstanding in this series, and that these also overlap. In the 243 women in the sterility group, these factors are bilateral tubal obstruction, 20.5 per cent; previous abortion, 16.46 per cent; uterine hypoplasia, 14.4 per cent; chronic endocervicitis, 16.04 per cent; pelvic peritonitis, 12.34 per cent, and salpingitis and perisalpingitis, 19.75 per cent. The remaining causes comprised a list of about twenty-five conditions. We have not included gonorrhea as such as an etiologic factor but have listed the pathologic conditions which we found resulting from this infection. Syphilis, on the other hand, is mentioned under both male and female causes, as gross genital changes due to syphilis are rarely observed. We were surprised to find so small a number of cases of sterility in our series in which the Wassermann and Kahn tests were positive.

MALE STERILITY

Male virility tests were made in 249 (83 per cent) of the entire series. The Hühner postcoital examination was made in 219 cases, a condom or ejaculate in 98 cases, and both postcoital and condom tests in 57 couples. No test for spermatazoa was made in fifty-one cases, chiefly for three reasons: First, the patient failed to return for the test in fourteen instances. Second, gross female pelvic pathologic changes sufficient to account for the sterile mating were found on physical examination in fourteen women, obviating the necessity of a sperm test until the female cause was removed. Third, in five instances there had been unsuccessful coitus (no intromission) because of intact hymen, even as long as five years after marriage! We are not publishing a list of male causes of sterility for the following reasons: First, it was not always possible to induce the male partner to report for a genito-urinary examination. Second, if the husband consented, he often chose to visit a urologist of his acquaintance, whose reports were often incomplete and indefinite. Third, the urologist sometimes reported on a condom specimen or ejaculate only, failing to report a local anatomic diagnosis. Fourth, only rarely was a constitutional fault reported in case of the male. Hence obesity, which appears as a diagnosis thirty-one times in the female list, was reported only twice in the diagnoses received from the urologist. This is obviously an error of omission.

THE POSTCOITAL TEST

In spite of the conclusions of Moench [11] that the postcoital test is not final, we have placed great stress on it and feel that it is essentially informative. The patient on whom a test is to be made is carefully instructed in accordance with the advice of Cary and Dickinson [12] regarding preparation and presentation at the office for Hühner's test. When a number of normally formed, actively motile spermatozoa are found in the mucus aspirated from the cervical canal from one to two and a half hours after coitus, we believe that the male is competent. He has proved his ability to deliver living

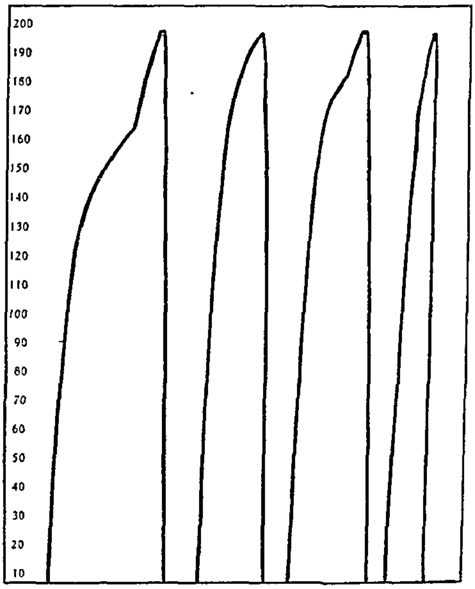

Fig. 2.—Kymographic tracing: apparent obstruction of fallopian tubes; slight shoulder pain and repeated test subsequently proved only partial obstruction in the one remaining tube. (Right tube removed previously.)

male elements into the environment favorable for their preservation. Here they may exist for many hours unmolested by acid secretions, and by means of their own motility the spermatozoids may reach the fallopian tubes, where fertilization of the ovum occurs. Constitutional faults, as Meaker and others have conclusively shown, may render the sperm relatively infertile, but with treatment the male fertility may be increased and the fertility threshold of the couple be raised. The vaginal pool is less of a criterion than the endocervical content. As a rule, a small fluid pool of grayish, milky fluid is found in the receptaculum seminis, and in favorable cases numerous actively motile, normally formed spermatozoids will be found after coitus. We have found them as long as four hours after coitus, still moving. On the other hand, the finding of only immotile forms in the vagina is a frequent occurrence and is not serious, provided a satisfactory sample is obtained by aspiration from the cervical canal. We have not considered it necessary or advisable to explore high up into the uterine cavity for samples. If our postcoital examination is not entirely satisfactory, a condom specimen or ejaculate is requested of the husband, also a urologic examination. Repeated Hühner tests after a week or two of abstinence from marital relations occasionally prove satisfactory after an initial failure. It is interesting to note that, in six cases in which no live spermatozoids were found in the cervix after coitus, the urologists' reports of condom specimens were satisfactory, but that, contrarywise, in no instance of a diagnosis of sterility from the condom specimen was a positive Hühner reaction found. This emphasizes the necessity of a condom or ejaculate check-up in all cases of negative postcoital examinations. It does not, however, negate the value of Hühner's test. We have found in many instances that the husband is willing to have his wife present herself for the postcoital test, although he himself is unwilling to be examined by a urologist.

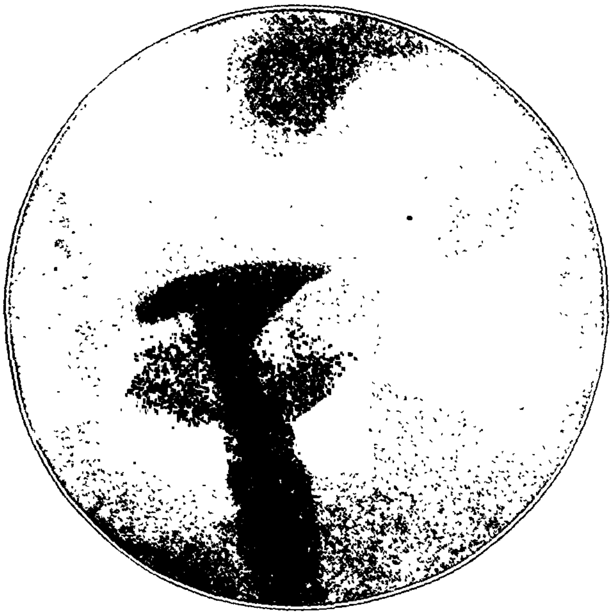

Fig. 3.—Transabdominal pneumoperitoneum reveals uterus and adnexa clearly. Iodized oil entered the right tube only. Apparent unilateral closure.

Many of the matings in which no male virility test was made proved fertile after gynecologic treatment was instituted, and pregnancy occurred before it was considered necessary to check up the Hühner and patency tests. This was particularly true in the cases in which there had been no previous intromission and in the amenorrhea group, to be referred to later.

TUBAL PATENCY TEST

Patency tests were carried out in 206 (68.6 per cent) of our patients. This included all the women in the infertility group and 149 (61.3 per cent) of the sterility group. Bilateral tubal obstruction was diagnosed in fifty women in the latter group. Of these, twenty-seven were fimbrial closures, as diagnosed by patency test and iodized oil, twenty-one were cornual, and only two were isthmial. Unilateral tubal obstruction was found in eight cases, in which five were cornual, two fimbrial and one isthmial.

No patency test was done in ninety-four women because: (*a*) a male cause for the sterility was discovered on the postcoital and condom tests; (*b*) gross female pathologic changes accounting for the sterility were discovered on bimanual examination, often of such a nature as to contraindicate the test; (*c*) the patient failed to return for the test. In seventy-nine women in this group, diagnostic pelvic pneumoperitoneum was done by the transuterine or transabdominal route, which proved of great value in clarifying the diagnosis. We (Stein and Arens[13]) have previously described the technic of this diagnostic procedure and have repeatedly emphasized its value, not only for a more precise diagnosis in sterile women but also for differential diagnosis in other puzzling gynecologic conditions. We have found pneumoroentgenograms, carbon dioxide being used alone or in combination with the instillation of iodized oil into the uterus and fallopian tubes, of the utmost value.

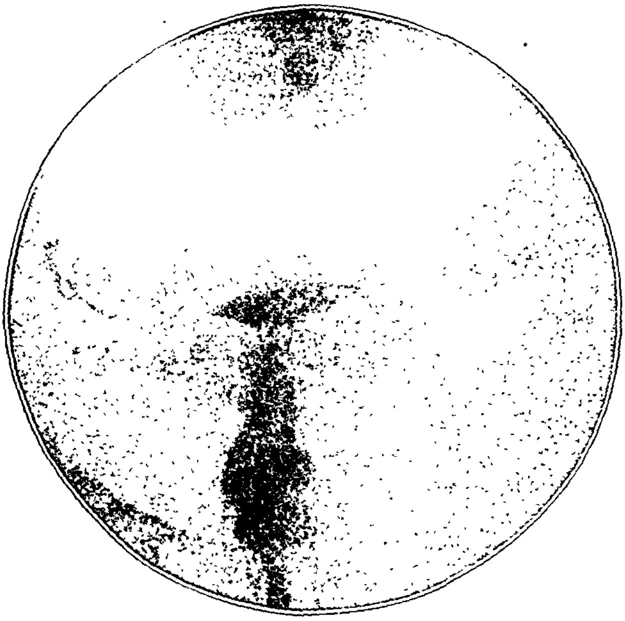

Fig. 4.—The same patient as in figure 3, one hour later. Both tubes were filled with iodized oil and the spill appeared from both fimbriated ends. (Unilateral or asynchronous spasm.)

It is with some hesitancy that we record a practice which we have adopted in a selected group of women. Following a verbal suggestion of L. Fraenkel of

[13] Stein, I. F., and Arens, R. A.: Radiology 7: 326 (Oct.) 1926; Iodized Oil and Pneumoperitoneum Combined in Gynecologic Diagnosis, J. A. M. A. 87: 1299 (Oct. 16) 1926; Radiology 8: 494 (Jan.) 1927; Am. J. Obst. & Gynec. 15: 707 (May) 1928; Radiology 12: 341 (April) 1929; Am. J. Obst. & Gynec. 18: 130 (July) 1929; Radiology 15: 85 (July) 1930.

Breslau during a visit which he made to this country some time ago, we performed the patency test immediately after a satisfactory postcoital test with the expectation of enhancing the possibility of pregnancy. This, of course, was done only in the presence of the conditions requisite for safety of the test, and one week after completion of the menstrual period. We do not feel, however, that pregnancy occurred sooner or in a greater number of cases than it would have occurred if the patency test had been done independently. We believe that the procedure is a safe one, provided the semen specimen is free from pus and bacteria, and no purulent endocervical secretion is present. There were no ill effects in approximately two dozen tests made in this manner.

Rubin has described the various phases of tubal patency so completely and has recorded his vast experiences so lucidly that we hesitate to devote much space to the subject. The question of the interpretation of tubal obstruction, however, merits some discussion. When the fallopian tubes prove patent on being tested with carbon dioxide, a characteristic graph is obtained (fig. 1) with the kymograph, or a subdiaphragmatic pneumoperitoneum may be observed with the fluoroscope. Shoulder pain usually ensues when the patient arises, but reliance on this symptom is not advisable. Neither should one rely on auscultation. When, however, there is obstruction to the flow of gas, the mercury manometer will show a gradual and steady rise to 200 mm., the advised limit of safety, and a different graph is obtained (fig. 2). This observation on a single test, however, does not necessarily signify a pathologic obstruction. Repeated patency tests with the utilization of antispasmodic drugs advised by Meaker many years ago have proved most useful in eliminating some of the spastic obstructions. The use of radiopaque oils, however, has done even greater service, for with the aid of an iodized oil one may observe fluoroscopically or record roentgenographically the filling or the failure to fill of one or both fallopian tubes.

We do not feel, as does Rubin, that the site of tubal obstruction can be positively located by the site, severity and radiation of pain. A great variation in sensibility exists among women, and often unreliable conclusions are drawn from the patient's complaint of pain. In eleven cases in this series, curves characteristic of bilateral tubal obstruction were obtained, but on repetition of the test by the instillation of iodized oil the fallopian tubes were found patent. Again, three cases in which patency was proved satisfactory with gas, and a transuterine pneumoperitoneum was induced, showed an apparent cornual obstruction to iodized oil. These are typical cases of cornual spasm. True bilateral obstructions can be definitely proved only on prolonged and repeated observation after instillation of iodized oil and after films taken at intervals over a twenty-four hour period. Spasm is initiated, as a rule, in the uterine cornua rather than in the tubal isthmuses. Evidence of asynchronous contraction of the uterine cornua and fallopian tubes is shown in cases of apparent unilateral obstruction (fig. 3) which on subsequent test or on laparotomy are found to be patent (fig. 4).

The use of pelvic roentgenograms taken after combined pneumoperitoneum and instillation of iodized oil often clears up the diagnosis in cases of questionable results by revealing a pathologic mass in one or both adnexa, or by clearly showing normal adnexa in cases of spasm. A complete discussion of the interpretation of roentgenograms by this method has previously been published by one of us.[14] From our experience with diagnostic pneumoperitoneum (600 cases in nine years), we would urge its more frequent use as an aid to gynecologic diagnosis. When this method is used in combination with the instillation of iodized oil, a maximum of information concerning the pelvic status may be obtained on the roentgen film, exceeded only by that obtainable at laparotomy. We have frequently checked up the roentgen observations, utilizing the combined method with those revealed at subsequent laparotomy, and have thus proved the accuracy and value of such films. On the other hand, we have often revealed a normal pelvic status on the roentgen film, obviating the necessity of laparotomy in cases of suspected pathologic changes. This procedure has practically eliminated the exploratory laparotomy in our practice. Underdevelopment and maldevelopment of the genital tract have been accurately demonstrated by us by this means; we have observed arcuate, bicornate, septate and double uteri, differentiated by means of the instillation of iodized oil and often associated unilateral and bilateral ovarian swellings which were clearly visualized by the pneumoperitoneum.

SURGICAL TREATMENT OF STERILITY

Of a total of 300 women examined for sterility in this series, 80 were treated more or less surgically (table 2). By far the greatest number were treated in the office, for the cure of chronic endocervicitis. We have employed the method of Dickinson, linear cauterization, with entire satisfaction, using a fine platinum loop about 1 inch in length, at cherry-red heat. Occasionally, cauterization required repetition after four or six weeks, and rarely there was troublesome bleeding after the cautery treatment. The end-result was extremely gratifying, leaving a normal appearing cervix, free from purulent discharge.

Table 2.—*Surgical Treatment in Sterility Group (Female)*

Type of Treatment		Cases
Linear cauterization of cervix		21
Dilation of hymen and vagina under anesthesia		2
Perineotomy*		1
Removal of complete vaginal septum		2
Trachelorrhaphy		1
Tracheloplasty (Sturndorf)		1
Curettage for polypi		2
Posterior colpotomy for abscess		1
Myomectomy		2
Hysterectomy (calcified fibroids)		1
Hysterectomy (irreparable inflammation)		4
Uterine suspension		1
Plastic resection ovary		6
Unilateral	4	
Bilateral	2	
Oophorectomy		12
Dermoid (unilateral)	2	
Tubo-ovarian disease (unilateral)	7	
Tubo-ovarian disease (bilateral)	3	
Salpingectomy		15
Unilateral	9	
Bilateral	6	
(4 with hysterectomy)		
Salpingostomy		5
Pregnancy followed		2
Separation of perisalpingeal adhesions		1
Total		80

We wish to call attention to the fact that the operation of dilation and curettage appears only twice on our list, and in both instances it was indicated by the presence of cervical polypi. In no case was the operation performed empirically as a curative measure. Uterine suspension was done only once in this series, although retroversion was found in eighteen cases. We do not

14. Stein, I. F.: Surg., Gynec. & Obst. **42:** 83 (Jan.) 1926; S. Clin. North America **7:** 777 (Jan.) 1927; Illinois M. J. **54:** 359 (Nov.) 1928; Am. J. Obst. & Gynec. **21:** 671 (May) 1931.

feel that uterine displacement is an important cause of sterility. If the postcoital test reveals that the cervix is not inseminated, then correction of the malposition is indicated. Postural treatment and pessary insertion prove satisfactory in a good proportion of cases. Plastic resection of the ovary was done in six instances in which one or both ovaries were found cystic. In one of these patients bilateral polycystic ovaries were resected after failure of organotherapy and dietary management. This woman was 25 years old, had been married four years, and was under treatment for sterility for almost a year. Transuterine pneumoperitoneum, after a successful patency test, revealed the fact that each ovary was almost the size of the uterine fundus and was irregular in outline. Menstruation had always been scant and irregular. At laparotomy the cystic portion, about three fourths of each ovary, was removed by wedge-shaped resection, and subsequently a course of female sex hormone was administered. Coitus was resumed two months after operation, and pregnancy occurred three months later. The patient delivered an 8 pound baby at term.

More or less skepticism has been shown on the part of conservative gynecologists concerning the advisability of performing salpingostomy in cases of closed fallopian tubes. After careful selection of cases, we performed this operation on five patients in our series (table 2). Pregnancy occurred subsequently in two of these patients (one and two years after) and was carried to full term in each instance. In none of the patients on whom we performed salpingostomy was tubal pregnancy observed, but in one patient under our care who had had a salpingostomy elsewhere and had delivered one normal full term child since the operation, a tubal pregnancy developed. If the tubal closure is fimbrial and due to old perisalpingeal adhesions, and the tubes are otherwise normal, salpingostomy is likely to be successful in about 10 per cent. This operation, however, should be undertaken only after the male partner has been found to be virile. After salpingostomy the tubes should be tested with gas or iodized oil at intervals to prove that they remain open. Other surgical procedures devised to obviate bilateral tubal obstruction, such as ovarian and tubal transplantations into the uterus, are usually failures and may prove disastrous.

MEDICAL TREATMENT

Another group of patients were treated essentially medically. These were the obese women, those with hypoplasia, amenorrhea or hypomenorrhea and those with nutritional disturbances. In the treatment of our patients we have emphasized the use of foods essentially rich in vitamin E, but we wonder how much value such a diet has in the human adult. There is no doubt of its value in experimental animals. In some of the obese patients having normal metabolism we have followed Meaker's advice to increase the amount of protein in the diet, with some success.

Patients complaining of amenorrhea and hypomenorrhea, whether they were associated with obesity or not, have been treated in the past with various endocrine substances with but little favorable result. More recently we used the female sex hormone preparations with a hope of success in this class of patients. The tablet form first used, by mouth, yielded no appreciable result. In the past year we have used a preparation of female sex hormone in ampules, each representing 100 mouse units (Allen and Doisy standard) administered intramuscularly in thirty-five women. Of twenty-eight of these in whom the essential complaint was amenorrhea, eighteen responded with more or less regular menses, four failed to menstruate, and six failed to report the results. Several of the women who responded to therapy with the female sex hormone had previously failed with ovarian, pituitary, corpus luteum, thyroid, estrogen, and other glandular extracts. One of them had taken roentgen therapy of the ovaries six months previously without result. Of the seven cases of uterine hypoplasia associated with hypomenorrhea or amenorrhea, five responded with increased menstrual function and a palpable increase in the size of the uterus.

Ten patients in this series complained of sterility in addition to amenorrhea, and five of these have become pregnant after treatment with the preparation of the female sex hormone. In these cases pregnancy was not recognized until two or three menstrual periods had lapsed, and the hormone treatment had been continued in pregnancy. They were first looked on as failures to relieve the amenorrhea, for the patients suffered no nausea or vomiting or other usual symptoms of early pregnancy. The breasts were slightly enlarged, but this symptom is commonly observed when using glandular preparations. Because of complete absence of nausea in these women who were previously treated with the hormone, the latter was given in daily doses of two ampules (200 mouse units) to five patients suffering with severe hyperemesis. In four cases the relief was strikingly prompt, a result we never observed when using corpus luteum. Although we realize that this represents a small series, from which definite conclusions may not be drawn, we do feel encouraged by our results, and we believe that the newer preparations of the female sex hormone are deserving of further trial.

PREGNANCY AFTER STERILITY INVESTIGATION

There can be no doubt that the patency test is of therapeutic as well as of diagnostic value. Of the fifty-seven matings classified by us as infertile, fifteen, or 26.3 per cent, of the women became pregnant after the patency tests, without other than dietary treatment and instruction in sex habits. Many of these conceived so promptly after proving patency of the tubes that the results must be credited to the insufflation. Others, again, conceived only months or more than a year after the test. These could not fairly be ascribed to any direct effect of the patency test. In some cases in which we found both of the couple competent but learned that the sex act had become more or less a matter of indifference and of infrequent occurrence, we have advised the reading by the husband and wife together of certain works on sex hygiene. These books serve as erotic stimulants by vividly portraying in detail the sex act, various postures for its performance, and even perverted practices, the adoption of which some of the authors recommend. Although the description of the latter is unnecessary and is revolting, and its inclusion in works on sex hygiene is regrettable, these books do serve a useful purpose in selected mating, despite this objectionable feature. In a small percentage of couples in our series we believe that the sexual awakening caused by the reading of carefully selected books on sex hygiene resulted in a greater interest in sexual practice, increased libido, increased frequency of orgasm and, shortly, in pregnancy. One of the couples mentioned had been married ten years without conception and had undergone repeated sterility investigations under various specialists without effect. Shortly after sex instruction was given by us the couple interested themselves in sex literature, and pregnancy occurred.

According to most authorities, about 10 per cent of all matings are barren. The 300 couples analyzed in this study fall into this class. As a result of our investigations and treatment. conception occurred in approximately one fifth (19.3 per cent) of the cases, which represents fifty-eight pregnancies.

Forty-three of these were in patients in the sterile and fifteen in the infertile group. The latter figure reveals a high proportion (26.3 per cent) of fertility in the group usually classed as sterile. Fifty of the pregnancies carried to full term, and five patients are in the first half of pregnancy at the time of this writing. Only three patients (5.17 per cent) aborted.

Table 3.—*Pregnancy in the Sterility Group*

			Years	Diagnosis		Treatment			
No.	Age	Primary or Secondary	Sterile or Since Last Pregnancy	*Female*	*Male*	*Female*	*Male*	Conception After Treatment	Termination
1	33	Primary	11	Hypoplasia; obesity	Normal	Patency; organotherapy	None	5 years	Abortion, 10 weeks
2	23	Primary	4	Hypoplasia; obesity	Normal	Patency; organotherapy	None	3 months	Term
3	20	Primary	2½	Suppuration of appendix with drainage	Normal	Patency; organotherapy	None	6 months	Term
4	28	Primary	2	Ovarian cyst	Normal	Removal of cyst	None	12 months	Term
5	31	Primary	11	Obesity; retroversion	Aspermia: atrophy of testes	None	None	2 months	Term (husband)
6	28	Primary	3	Fibroids; perisalpingitis	Normal	Myomectomy; bilateral salpingostomy; iodized oil	None	1½ years	Term
7	27	Primary	1	Not made	Oligospermia	Patency, 4/10/29	None	L. P. 7/24/29 (1 month)	Term
8	32	Primary	1	Barth. cyst; endocervicitis	Normal	Cautery; excision of cyst	None	1 month	Term
9	25	Secondary	2	Endocervicitis; perisalpingitis; retroversion	Normal	Gilliam suspension; salpingostomy	None	2 years	Term
10	26	Primary	3	Endocervicitis; obesity	Normal	Cautery; endocrine patency	None	2 months	Term
11	26	Primary	1	Endocervicitis	Normal	Cervix patency	None	5 months	Abortion, 2-3 months
12	34	Primary	16	Previous curettage	Oligonecrospermia; obesity	None	Thyroid and prostatic massage	2 months	Term
13	22	Primary	2	Obesity; amenorrhea	Normal	Organotherapy	None	1 month	Term
14	30	Primary	7	Endocervicitis	Normal	Cervix patency	None	2 years	Term
15	30	Secondary	2	Endocervicitis	Normal	Cautery patency	None	7 months	Term
16	25	Primary	1	Unilateral hydrosalpinx	Normal	Removal hydrosalpinx	None	3 months	Term
17	22	Primary	2	Obesity; hypoplasia	Normal	Organotherapy	None	9 months	Term
18	26	Primary	6	Hypoplasia; amenorrhea	Chronic vesiculitis	Endocrine patency	G. U. treatment	3 years	5-6 months pregnant
19	26	Primary	5	Endocervicitis	Normal	Cautery patency	None	3 months	Term
20	35	Secondary	4	Previous salpingostomy	Normal	Repeated patency; iodized oil	None	2 months	Ectopic
21	26	Primary	3	Endocervicitis	Normal	Cautery patency	None	2 months	Term
22	25	Primary	5	Intact hymen	Normal	Perineotomy	None	3 months	Term
23	20	Primary	1	Amenorrhea; Shus.	Normal	Female sex hormone	None	Menstruation once after five ampules	Term
24	24	Primary	4	Obesity; amenorrhea; dilation; ovarian cysts	Normal	Diet; bilateral resection of ovaries; female sex hormone	None	5 mos. after operation; female sex hormone	Term
25	31	Primary	10	Normal	Oligospermia	None	Massage of prostate	2 months	Term
26	30	Secondary	4	Obesity	Normal	Patency; organotherapy	None	5 months	Term
27	29	Primary	6½	Previous D. and C.	Normal	Patency 5/8/30	None	L. P. 7/8/30 2 months	Term
28	29	Secondary	3	Previous ectopic gestation with fever	Normal	Patency	None	4 months	Term
29	23	Secondary	2	Retroversion	Normal	Vaginal pessary	None	2 months after correction	Term
30	23	Primary	2	Vaginismus	Normal	Sex instruction: *dilation of vagina*	None	1½ years	Term (twins)
31	26	Primary	4	Endocervicitis	Normal	Cautery patency	None	6 months	Term
32	27	Primary	1	Double uterus and vagina	Normal	Removal septum vagina; iodized oil	None	1 mo. after operation	Term
33	31	Primary	3½	Fibroids	Normal	Patency 11/21/29	None	L. P. 1/31/30 2 months	Term
34	28	Primary	3	Retroversion	Normal	Patency; sex instruction; diet	None	2 months	Term
35	30	Secondary	3	Previous operations; abortion	Normal	Repeated patency	None	1 month	Term
36	25	Primary	2½	Obesity; endocervicitis	Oligospermia and necrospermia	Endocrine cautery	Prostatic *massage*	3 months	Term
37	26	Primary	2	Intact hymen	Normal	Perineotomy	None	2 months	Term
38	22	Primary	3	Amenorrhea 6 months	Normal	Female sex hormone; x-rays	None	No result from roentgen therapy; pregnancy during treatment with female sex hormone	Term
39	22	Primary	3	Vaginismus	Normal	Dilation of vagina	None	2 months	Term
40	23	Secondary	5	Retroversion	Normal	Posture; patency; exercise	None	6 months	Term
41	27	Secondary	3	Obesity; endocervicitis	Oligospermia	Organotherapy; cautery	Thyroid	1 mo.; husband treated with thyroid	2½ months pregnant
42	29	Primary	2	Amenorrhea	Normal	Female sex hormone	None	2 months	Term
43	35	Secondary	8½	Amenorrhea 5 months	Normal	Female sex hormone	None	1 month	Term (twins)

The pregnancies referred to include only a single gestation after the completion of the sterility study. There were, in addition, five patients who had more than one pregnancy after completion of the tests, and in one patient tubal pregnancy developed while she was in our care. This woman had had a salpingostomy previous to our investigations and had given birth to a full term child since the operation. One pregnancy included in our series occurred after a three year period of sterility following a tubal pregnancy.

SUMMARY

1. Three hundred couples presenting sterility problems have been examined and treated, and the results are analyzed. The importance of a rational sequence of investigative procedures is stressed.
2. We have excluded from the diagnosis of sterility all couples who meet with the fundamental requisites of fertility even though married three years or more. These were grouped under the classification of infertility.
3. Female causes were found in 89.4 per cent, male causes in 28.8 per cent, and both male and female in 18.1 per cent of the sterile matings.
4. The outstanding female causes were obstructions of the fallopian tubes, chronic endocervicitis, and uterine underdevelopment. Pathologic conditions leading to aspermia and necrospermia were chiefly the male faults.
5. Tubal patency tests were carried out in 206 women in this series. In the infertility group they were done in 100 per cent and in the sterility group in 61.3 per cent of cases. The interpretation of apparent tubal obstruction is discussed and the value of roentgenograms, combined uterosalpingography and pneumoperitoneum being used, is emphasized.
6. In the medical treatment of sterility one new substance has been found of value; namely, a preparation of the female sex hormone.
7. The surgical treatment of sterility has undergone complete revision. Linear cauterization for chronic endocervicitis was the most frequently used method in our series. Salpingostomy was done in five cases, carefully selected, with subsequent pregnancy in two.
8. Pregnancy occurred in 58 women after our investigation and treatment, or 19.3 per cent for the entire series of 300 women. In those grouped as infertile matings, pregnancy resulted in 26.3 per cent and in the sterile matings in 17.3 per cent.

ABSTRACT OF DISCUSSION

Dr. I. C. Rubin, New York: In spite of a demonstrable generative impotence of the husband, the question is sometimes raised by the wife for reasons entirely her own as to whether or not she may be suffering from some obstacle to conception. In such instances there can be no objection to insufflating the tubes and pursuing the investigation as completely as possible. There are many cases in which the investigation cannot be complete, for reasons already stated by the authors. In a series of over 3,000 in my sterility cases, 1,034 presented conditions contraindicating insufflation. An idea of the functional status of the tubes can be obtained in the ordinary routine performance of tubal insufflation, with the aid of the kymograph. Some of the slides that were shown demonstrated this. We have not only established the factor of tubal nonpatency or of tubal patency in these cases, but we have also learned to recognize what is normal patency, which is tremendously important, I think, in an investigation of the sterile mating. In a series of 2,136 cases in which insufflation was done, pregnancy occurred in 216 of my primary sterility group and in 134 of the secondary sterility group. If the nonpatency cases in both groups, i. e., 537 cases, are omitted, there is a pregnancy incidence of 20 per cent in the primary sterility group and of 24 per cent in the secondary sterility group. I agree with Drs. Stein and Leventhal that the time interval generally accepted as designating a sterile marriage is perhaps too arbitrary. This is particularly true in the cases of elderly couples who cannot lose much time in seeking aid and getting it. In the cases with amenorrhea, I have had to resort to roentgen treatment by fractional doses. In a series of fifty-five cases I have had twenty-six pregnancies. Drs. Stein and Leventhal may be congratulated on the results obtained in such cases by the use of the newer hormonal extracts. If their results can be reproduced by others, we shall be in possession of a specific hormonal remedy which has been long awaited in this class of functionally depressed sterile women.

Dr. Philip H. Smith, Evanston, Ill.: I frequently find that patients are surprised to learn what constitutes the routine investigation of sterility and that the observation may take weeks, months, perhaps a year or two years. For that reason I have found useful a small card of printed instructions, given to the patient on the first visit, briefly outlining about what I expect to do and what I expect of each member of the union. This seems to stimulate interest, and the patient knows what to expect. I believe with Drs. Stein and Leventhal that too much stress cannot be placed on the postcoital test. The presence of active, motile spermatozoa of normal morphologic structure in the cervical canal can leave little doubt as to the competence of the male. However, in a certain number of cases in which there are no demonstrable pathologic changes and in which the tubes are patent, as demonstrated by the insufflation test, I believe one is correct in presuming that the male has a lowered fertility, and I like to make a study of his specimen myself. Finding it abnormal, I refer him to the urologist for treatment. Instructions as to diet, exercise, sexual activity, I like to give myself. I believe that these instructions are of great importance in cases of lowered fertility. The injection of iodized oil is highly beneficial in cases in which the diagnosis is a little obscure, and in the presence of tubal obstruction it will definitely locate it. However, I believe it should follow the third, certainly the second, insufflation test because of the added information to be gained by repeated tests and because of the therapeutic value of the test. Foci of infection in the teeth, tonsils, sinuses, and so on play an important part in abortion and the toxemias of pregnancy, and they may have something to do with puerperal fever. I don't believe it is wrong to assume that they play an equally important part in sterility in a great many cases. One of the earliest steps one should take is to have these foci carefully checked. I do not believe that salpingostomy should be resorted to as a means of curing sterility except, as stated by Dr. Curtis, in cases in which the motive for operation is relief of pain or distress.

Dr. Charles Mazer, Philadelphia: Amenorrheal and irregularly menstruating women are admittedly of low fertility. Regularly menstruating sterile women in whom one cannot find an ascertainable cause for the existing sterility present a problem in diagnosis. These women, as a rule, do not show evidence of genital hypoplasia. In order to eliminate an endocrine factor, I have subjected forty-two of these patients to a premenstrual curettage and have simultaneously abstracted 80 cc. of venous blood to ascertain the level of female sex hormone. The test was performed in duplicate. Twenty-five of these regularly menstruating sterile women did not show any microscopic evidence of a nidatory endometrium; and only four of the twenty-five showed a demonstrable quantity of female sex hormone in the blood. The lack of the nidatory endometrium in these women is indicative of faulty luteinization. Some of the patients presented stigmas of an existing endocrinopathy. The majority, however, appeared normal. The close relationship between a negative Frank and Goldberger test and an absence of the nidatory endometrium in this class of women shows that there is no actual need to perform a premenstrual curettage; the Frank and Goldberger test when performed in duplicate is apparently sufficient in the diagnosis of endocrine sterility in regularly menstruating women.

Dr. Raymond E. Watkins, Portland, Ore: The authors state that 36 per cent or thereabouts of the patients were sterile because of inflammatory conditions in the pelvis. Another statement regarding these inflammatory conditions or, rather, the occlusions of the lumen of the tube was that the occlusion occurred in the interstitial portion of the tube in the majority of the instances according to the injection of iodized oil. Last year, in a study of fifty fallopian tubes removed at the time of operation, it was found that the majority of inflammatory occlusions occurred in the isthmian portion of the tube rather than in the interstitial; that the next largest proportion was in the interstitial, and the fewest in the fimbriated portion of the ampullar part, or the fimbriated end of the tube. The type of the occlusion was usually a circular constriction due to an inflammatory reaction of the tube as a result of the infection. In gonorrhea there is a tendency for the infection to extend below the mucosa, not only destroying the mucosa but extending into the musculature, producing small abscesses. The latter were demonstrated by the injection of bismuth into the tube, showing multiple diverticula running down into the healed abscess cavities in the musculature. As a result of this infection there is the formation of a good deal of scar tissue, which secondarily contracts, producing the constriction or occlusion. I am discussing this phase of the subject largely to show the futility of attempting to overcome the obstruction in the isthmian portion of the fallopian tube by operation. Operative procedures do little or no good. Time is the great element here in the cure of these infections. Any one who has watched these women for a period of time knows that eventually a few become pregnant but not a great many. The postabortal infection is a different type. It affects the peritubal structures and the cellular tissue, and is not a mucous membrane destroyer. It sometimes produces external adhesions that will constrict the fallopian tube and obstruct its lumen. If the fimbriated end of the tube can be gently opened by the use of the hemostat or blunt instrument, provided the interstitial and isthmian portions are patent and can be carefully spread apart, I think this procedure offers considerable hope of overcoming the obstructing lesion.

THE SURGICAL TREATMENT OF URINARY INCONTINENCE IN THE FEMALE *

NORMAN F. MILLER, M.D.
Professor of Obstetrics and Gynecology, University of Michigan Medical School
ANN ARBOR, MICH.

Progress in the treatment of urinary incontinence of the female is essentially a story of surgical growth and development. Beginning in the eighteenth century with crude operations for the correction of vesicovaginal fistulas, the scope of this type of plastic surgery has so broadened that today most of the congenital and acquired bladder deformities are successfully treated by surgical means.

From a practical point of view, it would seem desirable to eliminate methods which appear to be basically unsound and encourage refinement and use of operations already proved.

Regardless of the explanations given by the originators of the various operations, investigation fails to indicate convincingly on just what the successful result depends. Continence following repair of the torn or relaxed internal bladder sphincter may simply be a matter of narrowing the urethral lumen. Success following plaiting of the pubovesicocervical muscle sheet (external sphincter) has been attributed to replacement of the sagging urethra and bladder. Likewise, relief following the use of muscle transplant operations is not necessarily dependent on continued function of the transplanted muscle, for it has been demonstrated that satisfactory results may follow the use of fascial strips without muscle.

In attempting to eliminate the less desirable operative procedures, this unsettled situation must be taken into consideration; consequently, for purposes of this paper, the selection is based primarily on functional improvement following the use of different operations.

Before the surgical treatment of urinary incontinence is discussed further, it is important to consider its etiology. In some patients the cause is quite obvious while in others diligent search may fail to place the responsibility. In general, the more common causes are thought to be congenital malformations of the lower urinary tract, acquired or congenital weakness of the sphincter muscles, and injury to the neuromuscular apparatus responsible for bladder control. Since successful surgical correction is fundamentally dependent on a thorough understanding of the cause, every effort should be made to uncover the responsible factors. To this end the history, particularly the time of onset, is important; but the patient's statements should not be depended on too much. Examination should include thorough study of the urinary tract as well as roentgen examination of the lower spine. The presence of spina bifida occulta or other malformation of the lower spine should always be viewed in the light of possible cause and effect relationship. Only by careful study may small fistulas, aberrant ureters and spinal cord lesions be discovered and appropriate treatment advised. It must also be remembered that there may be considerable overlapping of the ordinary enuresis of childhood and true urinary incontinence. Because of the many conditions presumably responsible for incontinence and in order to delimit the scope of this paper, it must be pointed out that the term incontinence as here used applies only to leakage from an intact urinary tract. Consequently, exstrophy, epispadias, aberrant ureters and acquired urinary fistulas will not be considered at this time except so far as patients so afflicted fail to become continent after operative correction of the primary lesion. With this understanding, the causes of urinary incontinence may be divided into three groups, thus:

Group 1.—*Incontinence Due to Congenital Absence or Weakness of the Control Mechanism.*—Incontinence persisting after the surgical correction of congenital bladder defects belongs in this group. With improvement in operations for the correction of bladder malformations, this group will tend to disappear, most surgeons realizing that control is just as important as restoration of the deformed viscus. Congenital absence or weakness of the sphincter muscles unaccompanied by other urinary tract disease is uncommon and accounts for but few cases.

Group 2.—*Incontinence Due to Local Trauma with Impairment of the Control Mechanism.*—In this group are included such common causes as parturitional injuries to the bladder sphincters, sagging of the urethra,[1] loss of muscle tone, and senile changes. All degrees of incontinence are noted. In older women slight incontinence at the time of straining, coughing or sneezing is so common as to be ignored by the patient. Indeed, unless they are specifically questioned concerning this symptom, the true state of affairs may pass unnoted. Local injury at the time of parturition is considered the most common single cause of this deplorable condition. The symptom may appear immediately after confinement or may come on gradually after a period of years. The fact that a multipara may go for years before there is any evidence of leakage suggests loss of muscle tone, with advance in years as a contributing factor.

* Read before the Section on Urology at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 11, 1931.

[1] Bonney (On Diurnal Incontinence of Urine in Women, J. Obst. & Gynec. Brit. Emp. **30**: *358-365 [Autumn] 1923*) and Watson (Imperfect Urinary Control Following Childbirth and Its Surgical Treatment, Brit. M. J. **2**: *566-568 [Sept. 27] 1924*) feel that sagging of the anterior portion of the urethra is one of the most important factors responsible for urinary incontinence.

Group 3.—*Incontinence Due to Lesions of the Nervous Mechanism Involved in Bladder Control.*—The relationship between incontinence and certain cord lesions, whether injury, tumor, deformity or infection, has long been recognized. The hope for cure in these cases lies in correction of the cord condition, but when this is impossible, use of one of the operative procedures to be described may contribute greatly to the patient's comfort.

While the understanding of the nervous mechanism controlling the bladder sphincters is far from complete, the possibility of local nerve injury at the time of confinement sufficient to interfere with normal control deserves more than passing mention. The principal nerves to the bladder come from the second, third and fourth sacral nerves and from the sympathetics. After intermingling in the hypogastric plexus they follow the course of the ureters to reach the bladder. In addition, an automatic nerve control mechanism within the bladder itself is suggested by experimental work. Thus Rose and Deakin[2] point out that emptying of the bladder may be related intimately to the quantity of urine in the bladder, and, according to Kretschmer,[3] von Zeissle has pointed out that the dog bladder isolated from all nerve connections is still able to hold and expel urine. Consequently, it is not beyond the range of possibility that, with so much of the control mechanism centered in or near the bladder, trauma incident to confinement may in some instances be sufficient to cause local damage to the nervous control mechanism. Probably no amount of sphincter plaiting will correct the incontinence in these patients, and the fact that it does persist after repeated operations of this sort, all of which showed satisfactory surgical union, tends to corroborate the idea of local nerve injury. At any rate this possible relationship warrants further consideration by the scientifically inclined as well as the practically minded surgeon. It suggests the inadvisability of repeated plastic operations on the sphincter in the same individual, and tends to establish the rationale of muscle transplant when local nerve injury is suspected.

OPERATIVE PROCEDURES

Many operations suggested have not had sufficient trial to establish their worth. As a rule the more successful procedures are based either on sphincter tightening or on muscle transplantation. Other methods, though ingenious, are still in the experimental stage and their place in the treatment of incontinence remains to be determined. Judging from available records of successful results, the preferred methods may be classified as follows:

1. Plastic operations on the bladder sphincters:
   (*a*) Extravesical.
   (*b*) Intravesical.
2. Muscle transplant operations:
   (*a*) Rectus abdominis with or without fascia.
   (*b*) Pyramidalis muscle with rectus fascia.
   (*c*) Levator ani muscles.
   (*d*) Gracilis muscle.
   (*e*) Other muscles.

By the operations included in group 1, it is hoped to restore continence through repair, plaiting or tightening of the traumatized and relaxed bladder sphincters. Most operations of this type are of the extravesical type. They may consist in simple tightening of the internal sphincter at the bladder neck, as described by

Kelly and Dumm[4] in 1914, or in plaiting of both internal and external sphincters, as described by Edward L. Young[5] in 1922. When there is considerable relaxation of the pubovesicocervical muscle sheet, as seen in association with cystocele, a more extensive operation is necessary. Most of the procedures for this purpose are based on the principle of sphincter tightening plus restoration of bladder support. Sometimes the interposition of the fundus of the uterus (interposition operation) is advisable for the satisfactory elimination of the cystocele and the correction of the incontinence.

Some operators prefer the bladder approach for sphincter repair or tightening. For this purpose the technic described by H. H. Young,[6] Smith[7] and others has given satisfaction. My own preference is for the extravesical type, which has the advantage of permitting plaiting or tightening of both internal and external sphincters as well as replacement of the sagging bladder and urethra. The vaginal approach also eliminates the necessity for suprapubic drainage, the importance of which, in my opinion, has been greatly overemphasized. In the majority of instances, satisfactory surgical healing will occur with equal facility and without jeopardizing success if an appropriate sized indwelling urethral catheter is used during the first week following operation.

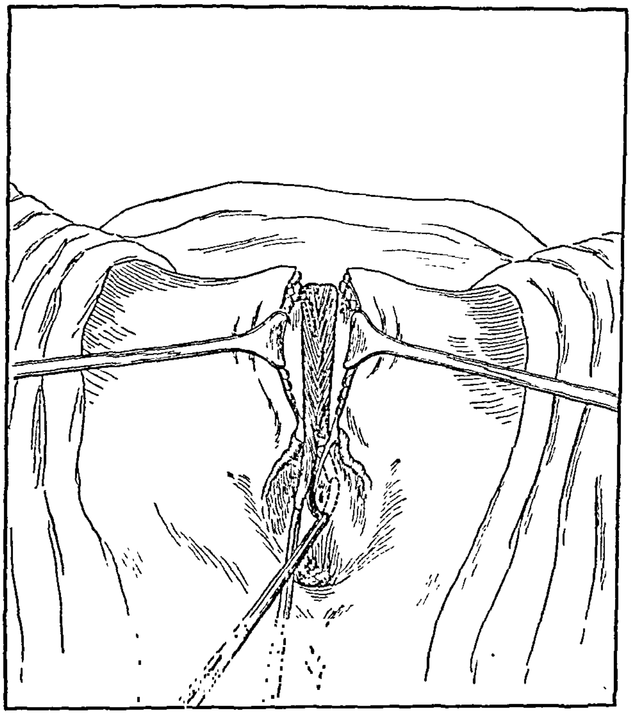

Fig. 3.—Muscle-fascia strips in place, split ends being around the urethra.

Muscle transplant operations have seemingly failed to receive the attention they justly deserve. This apparent neglect is the result of unfamiliarity with operations of this type and perhaps a growing interest in ureteral implantation into the bowel. Surprisingly few modern urologic and gynecologic textbooks even so much as mention operations of this character. It is no disparagement of the ureteral transplant operation to say that its use in the treatment of urinary incontinence in the female is seldom justified. Even with newer refinements, the margin of safety, both immediate and remote, is still too great to warrant its use except as a last resort.

The operation first described by Goebell[8] in 1910 and later improved and popularized by Stoeckel was one of the first muscle transplant operations to be used for the cure of urinary incontinence. It consists in bringing strips of rectus abdominis or the pyramidalis muscles with rectus fascia down behind the symphysis to encircle the urethra. The success of this and similar operations is generally attributed first to the fascia and secondarily to the muscle. Stoeckel[9] and Franz[9] consider persistent function of the transplanted muscle a matter of doubt and feel that the satisfactory results associated with its use are largely due to the support given the urethra. The question is still an open one, however, as evidenced by the fact that Rubsamen[9] proved persistent activity of the transplanted muscle four years after operation. Many modifications of the transplant operation are noted. Thus, Thompson[10] transplants the rectus muscle over the symphysis pubis and around the vulva with satisfactory results, and a somewhat similar use of the pyramidalis muscle and rectus fascia is described in this paper. The Goebell-Stoeckel operation and modifications thereof have been used extensively and successfully. Thus, Stoeckel[11] in 1921 reported nine cases with no loss of control years after the operation. Fragenheim[9] reported three cases of incontinence of central origin improved by this method of treatment.

Taussig[12] used the levator ani muscle. In future cases he proposes the use of the muscles from both sides. Similar use of this muscle is reported by Franz.[9]

Deming[13] successfully transplanted the gracilis muscle of the right leg.

CHOICE OF OPERATION

In patients with incontinence due to parturitional trauma (group 2), especially the milder forms indicated by partial bladder control, one of the less extensive sphincter plaiting operations should be tried. Generally, the results will be satisfactory; but in case of failure (nerve injury?) one of the several muscle transplant operations should be utilized. All too often the surgeon persists in the use of plastic procedures on the sphincter till the patient, firmly convinced that her condition is incurable, refuses further treatment. In the more extensive injuries associated with cystocele it is quite as important to tighten both internal and external bladder sphincters as it is to restore the bladder to its normal position, a fact frequently neglected and responsible for persistent incontinence after this type of plastic work.

Incontinence persisting after the correction of epispadias is best treated by muscle transplant, since in these cases there often exists an associated congenital weakness or absence of sphincter fibers. Colpocleisis and ureteral transplantation are not justifiable except as a last resort. The former is obsolete, while the risk in the latter, both immediate and remote, is still too great to warrant its use without first attempting relief by other means. Some may object to this on the basis that the technic of ureteral transplantation is now sufficiently standardized to remove it from the group of hazardous procedures. Even if this were true the ultimate fate of individuals thus treated is so unsettled that the operation should be reserved for patients who cannot be cured by less extensive operations.

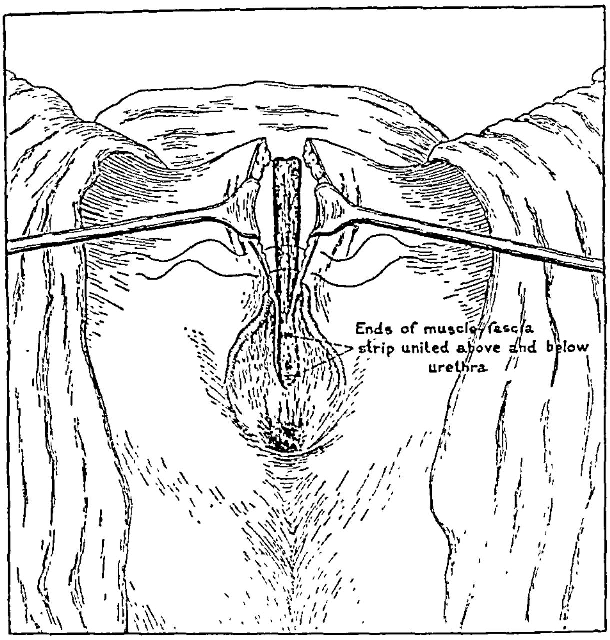

Fig. 4.—Muscle-fascia strip in place. Ends of muscle-fascia strip united above and below urethra.

In every case greatest care should be observed in determining the cause of incontinence and in selecting an appropriate operation for its correction. By so doing the necessity for repeated surgery on the same patient will be minimized and the chances for cure greatly enhanced.

While in the transplant operations the muscle of choice will depend somewhat on circumstances, it seems that use of the rectus abdominis, or pyramidalis, if present, is most logical, especially in the light of the many successes already reported. Apparently the chief objections to the Goebell-Stoeckel operation are bleeding and the excessive manipulation necessary in bringing the muscle-fascia strips down behind the symphysis between the pubis and the bladder. The modification of this procedure, as I have successfully carried it out, whereby the muscle-fascia strips are carried over the symphysis, would seem to minimize these potential drawbacks without jeopardizing the chances for success. The extensive incision and dissection necessary in transplanting the gracilis muscle and the possible interference with flexion and adduction of the thigh are tangible objections to this particular operation.

The effect of subsequent pregnancy and confinement on the permanence of control, once it has been established by surgical means, is still an open question. Mandelstamm[14] reported no return of the symptom following normal confinement in a woman treated by means of the Goebell-Stoeckel pyramidoplasty, and Calmann[15] noted continued control following forceps delivery in a patient similarly treated. Reports of this character, however, are rare; and until sufficient evidence is available to indicate the safety of delivery by the vagina, cesarean section should be advised.

REPORT OF CASE

Mary R., aged 5, was admitted to the gynecologic service of the University of Iowa, Oct. 23, 1930, because of complete urinary incontinence. According to available information the child was born with congenital "absence of the urethra." This was corrected by Dr. Frank A. King of Benton Harbor, Mich., in 1927, who also planned to remedy the persistent incontinence at a second operation. The patient failed to return, however, and apparently did not seek further advice until the time of her admission to this clinic.

A general physical examination revealed nothing unusual except some scarring over the symphysis pubis and around the infantile clitoris. There was moderate reddening and excoriation of the skin around the vulva due to irritation from continuous dribbling of urine. The urethra was intact but appeared toneless, suggesting the absence of sphincter fibers. A roentgenogram revealed a split pelvis and a small spina bifida occulta. The bladder capacity was 20 cc., and urinalysis was negative. Bladder contractility was good and there was no evidence of muscular atrophy. A small almond-sized calculus found in the vagina was readily removed with thumb forceps.

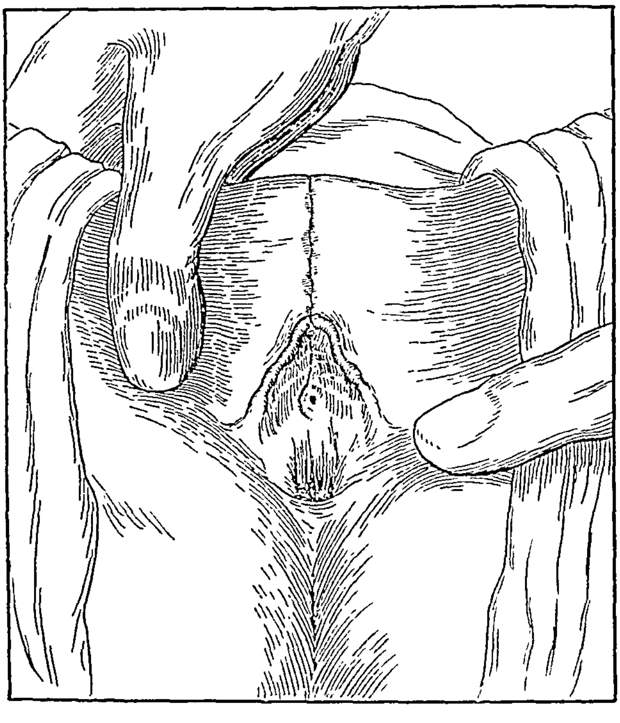

Fig. 5.—Healed incision, two weeks after operation.

After local treatment to the inflamed areas the patient was operated on, Nov. 19, 1930, as shown in the illustrations. A 10 F. catheter was left in the bladder for seven days; following its removal, she was catheterized at frequent intervals to prevent overdistention. By December 4, the patient was completely continent except for an occasional night wetting.

By modifying the Goebell-Stoeckel operation, extensive dissection and packing for hemorrhage were avoided. Furthermore, in giving support to the urethra and anterior portion of the pubovesicocervical muscle sheet this factor in the etiology of incontinence was eliminated.

After discharge from the hospital the patient was able to attend school and play as any other healthy youngster.

In the early part of March, 1931, she was called back to the clinic. At that time she was completely continent during the waking hours but was generally damp once during the night. Because of an attack of follicular tonsillitis at this time it was necessary to admit her to the hospital until completely recovered. During her illness fluids were forced as part of the routine treatment for the throat condition, but no change in the patient's ability to control the urine was noted. Neither was there any increase in the nocturnal wetting. The average amount of each voiding was 60 cc.

At this time it was learned that the child was not living with her parents but was staying with relatives, who apparently made no effort to teach her to use the toilet during the night. With time and training it is not unreasonable to expect that she will become completely continent.

One might well query the cause of the night wetting in this patient. Perhaps the control noted during the waking hours is due to conscious effort and the night wetting to relaxation of the still incompletely trained muscles substituting for the natural sphincters.

THE VALUE OF NEUROSURGERY IN CERTAIN VESICAL CONDITIONS *

JAMES R. LEARMONTH, M.B., Ch.B., Ch.M., F.R.C.S. (Edin.)
ROCHESTER, MINN.

Three sets of nerves reach the bladder itself, its sphincter apparatus and the posterior urethra. Two of these sets belong to the autonomic system, a pathway derived from the thoracicolumbar outflow of the autonomic system, and a pathway derived from its sacral outflow. The former is usually termed sympathetic; the latter, parasympathetic. The remaining set (pudic nerves) belongs to the somatic system, and arises from sacral segments of the spinal cord.

Thoracicolumbar Outflow.—The origins of the fibers forming the thoracicolumbar outflow are shown in figure 1. They are finally concentrated in the presacral nerve, or superior hypogastric plexus, which has a superficial position under the peritoneum in front of the last lumbar vertebra. More than half of the total number of fibers in the presacral nerve are medullated preganglionic fibers, which are chiefly the downward continuations of mesially directed branches from the lumbar sympathetic ganglions; the nonmedullated fibers appear to be, at least in greater part, downward continuations of the branches from the upper abdominal visceral sympathetic ganglions. Below the promontory of the sacrum, the presacral nerve divides into the two hypogastric nerves, each of which joins the corresponding hypogastric ganglion. Relatively small bundles join the hypogastric ganglions from the second and third sacral ganglions of the lateral sympathetic chains.

With the cooperation of my colleagues of the Section on Urology of the Mayo Clinic, I have, during operations on human beings, stimulated the presacral nerve with a faradic current, while a cystoscopist noted the results. In a series of six cases, the following effects could be demonstrated:[1] (1) closure of the ureterovesical orifices; (2) contraction of the trigon; (3) contraction of the internal sphincter; (4) contraction of the musculature of the prostate gland; (5) contraction of the musculature of the ejaculatory ducts and seminal vesicles; (6) contraction of the blood vessels of the trigon, and (7) sensations of pain, felt in the region of the bladder. In addition, by studying the effect of the intravenous injection of epinephrine on the tension in a normally innervated bladder, I was able to show that sympathetic nerves exert an inhibitory action on the expulsive musculature of the bladder. These nerves have been aptly termed by Rose the "filling nerves" of the bladder.

The effect of division of the presacral nerve on the function of the bladder is to diminish the tonus of its internal sphincter and to increase its expulsive power. Because the internal sphincter later recovers some of its tonus, I am inclined to agree with Gaskell that the site of the synapse in this part of the nerve pathway is in the muscle itself. The synapse in the course of the inhibitory fibers is probably situated in the hypogastric ganglions.

Sacral Outflow.—The fibers that belong to the sacral outflow arise from the anterior primary divisions of the second, third and fourth sacral nerves. In animals, the homologous nerves are the pelvic nerves (Langley) or nervi erigentes (Eckhardt). These nerves join the hypogastric ganglions and probably pass through them without synaptic interruptions. The parasympathetic nerves contain fibers which: (1) initiate and increase the action of the expulsive musculature of the bladder; (2) probably directly inhibit the internal sphincter; (3) convey afferent impulses for the micturition reflex; (4) convey impulses subserving such sensation as the bladder possesses, and (5) furnish part of the sensory innervation of the posterior urethra. These nerves are therefore the "emptying nerves" of the bladder.

The ultimate nerves to the bladder consist of from eight to ten branches, which leave the anterior border of each hypogastric ganglion. These strands contain fibers derived from both thoracicolumbar and sacral outflows; the two sets are not separable after they have joined the hypogastric ganglions. The exposure and identification of the sacral outflow present so great anatomic difficulty that, in the rare cases in which one wishes to interrupt this pathway, it is best carried out by resection of the anterior branches of the hypogastric ganglions.

Pudic Nerves.—The pudic nerves are said to supply some sensory fibers to the posterior urethra; they also provide motor fibers for the external sphincter. The functional importance of the external sphincter varies with sex; in the male, it has an active part in controlling the urinary stream, and after certain operations about the neck of the bladder may be the only structure which secures continence. In the female, the external sphincter does not appear to have the same functional importance, and its motor nerves may be divided without fear of subsequent incontinence.

SURGICAL EXPOSURE OF THE THORACICOLUMBAR OUTFLOW

The thoracicolumbar fibers are most easily exposed at their confluence to form the presacral nerve. This lies in front of the aortic bifurcation and the body of the

fifth lumbar vertebra, immediately under the peritoneum, and is separated from the great vessels by loose areolar tissue. In structure it varies from a loose network of fibers to a solid cord. The steps in the exposure of the nerve have been described by Cotte[2] and others. After subumbilical laparotomy, the posterior parietal peritoneum is opened in the median line, over the front of the fifth lumbar vertebra; often the individual strands of the nerve may be seen. I have been in the habit of working from the left side to the right; the dissection is continued until the left common iliac vein, and the right common iliac artery, have been isolated from all nerve filaments passing downward and mesially. A segment of the nerve from 3 to 5 cm. in length is then removed, and the central and peripheral stumps are ligatured. If it is desirable to interrupt the sacral rami communicantes and the paravertebral sympathetic chains also, as suggested by Pieri[3] for cases in which relief of vesical pain is the primary object of the operation, these structures are reached by dissecting outward under the flaps of parietal peritoneum. When the operation has been completed, the posterior peritoneal incision is closed by a continuous suture of catgut.

INDICATIONS FOR SYMPATHECTOMY IN VESICAL DISEASE

Paralysis of the Bladder.—My original operation[4] for vesical paralysis was undertaken on the hypothesis that deficient emptying of the bladder, due to injury to the sacral autonomic outflow, might be corrected by interruption of the thoracicolumbar outflow, so that the viscus was freed from the inhibitory influence of this set of nerves. The results of eight such operations have strengthened this hypothesis to a theory. Three operations are so recent that only the immediate results can be stated; of these, one was immediately successful, one encouraging, and one apparently without benefit. The salient features of the remaining five cases are as follows:

Case 1.—A man, aged 36, had difficulty in emptying the bladder, with residual urine of about 250 cc. On cystoscopic examination, he was found to have a typical "cord bladder"; neurologic examination traced this condition to the residue of infective myelitis of twelve months' duration, located in the sacral segments of the spinal cord. Operation was undertaken on the hypothesis that as a result of injury to the sacral autonomic outflow there was a nervous overbalance in favor of the thoracicolumbar outflow, and that interruption of the latter pathway would facilitate the emptying of the bladder. After operation the patient was able to empty the bladder completely. A year later he returned to be reexamined; the cure was maintained, and the most residual urine found at any examination was 20 cc. Moreover, by intravenous urography it was found that the upper part of the urinary tract was not dilated.

Case 2.—A boy, aged 8 years, in 1925, at the age of 3 years, had an illness of sudden onset, characterized by weakness and ataxia of the legs and by urinary retention. After three months, power in the legs returned, but the weakness of the bladder persisted. For five years, he was catheterized three times a day; in 1926 residual urine for a week averaged 1,840 cc., and by 1930 it had increased to 2,640 cc. On examination, it was found that the bladder was large and atonic. The boy could not tell when the bladder was full, and he wet his bed at night. The largest amount of urine that was passed voluntarily was 60 cc. A neurologic cause for the urinary retention could not be detected at this time. After resection of the presacral nerve, he rapidly and completely recovered the power of emptying the bladder. Two weeks after operation he could pass as much as 250 cc. voluntarily. He no longer wet his bed, as he awakened when the bladder filled. A year after operation, his cure is maintained; he empties the bladder completely and is in excellent general health.

Case 3.—A youth, aged 20, had had trouble with urination for two years; apparently the difficulty was a sequel of an attack of scarlet fever. He had to strain to start the stream and had episodes characterized by chills and fever. At the urologic examination, a typical "cord bladder" was found, with 240 cc. residual urine. As a roentgenogram showed a notch in the arch of the first sacral vertebra, this region was first explored; evidence of compression of the cauda equina was not found. Five days later the presacral nerve was resected. A month after operation, there was 20 cc. residual urine, and the expulsive force of the bladder was improved.

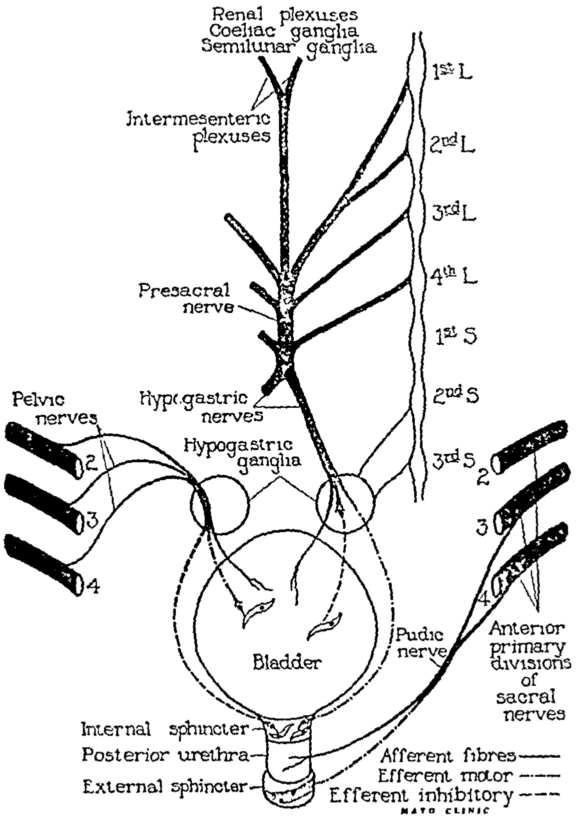

Fig. 1.—Anatomic diagram of nerves to the bladder.

Case 4.—A man, aged 28, had nocturnal enuresis until he was 23. For eighteen years he had frequency and occasional burning on micturition. For four years he had attacks of pain in the left loin, like those of renal colic. On urologic examination he was found to have a typical "cord bladder," with residual urine which varied in amount from 50 to 210 cc. The region of the cauda equina was first explored, and a firm fibrocartilaginous band at the level of the first sacral vertebra was dissected off the dural sac. This procedure afforded him little or no relief, and seven months later he returned for resection of the presacral nerve. Reexamination at this time showed that the amount of residual urine was about 120 cc. One month after operation the residual urine measured 20 cc., and the expulsive power of the bladder was improved.

Case 5.—An unmarried woman, aged 40, had had bilateral pyelectasis and ureterectasis for twenty-five years, as a result of incomplete emptying of the bladder. The process was probably of congenital origin. It declared itself in periodic attacks of fever, chills, and difficulty in urinating; during these attacks, a large amount of residual urine was present. On cystoscopic examination, in addition to the inevitable cystitis, the ureters were found to enter the dilated bladder in such an oblique fashion as to cause obstruction to the downflow of urine. Operation was undertaken in this case, in an endeavor to improve the expulsive force of the bladder. In this it has been successful, for Dr. D. K. Rose of St. Louis, to whose care the patient returned, has found that the capacity of the bladder has been diminished, and its expulsive power increased. Some additional procedure may be required to deal with the abnormal insertions of the ureters.

---

Thus two of the five patients remain cured after a year, and the remaining three have been benefited by the operations. The outlook for untreated cases of this type is so discouraging that less success than has been achieved would have justified the operations. Cases selected for operation must fulfil certain conditions. Thus, they must show evidence of injury to either the central or the peripheral part of the parasympathetic pathway, in the presence of an intact sympathetic pathway; the patient must be continent, and renal function must be satisfactory. All the cases described fulfil these conditions. In addition, I am anxious to test the effect of the operation in a case of the vesical paralysis which occasionally complicates removal of the rectum.

Vesical Pain

Age	Sex*	Nature and Duration of Condition	*Operation*	Time Since Operation, *Months*	*Result*
29	♀	Interstitial cystitis 6 years; capacity 250 cc.	Resection of presacral nerve	9	Pain relieved on one side only; frequency unaltered
40	♂	Interstitial cystitis 5 years; capacity 60 cc.	Resection of presacral nerve	8	No relief of pain or frequency
35	♀	Interstitial cystitis 2 years; capacity 90 cc.	Resection of presacral nerve	7	Some relief of pain and frequency (about 40 per cent)
49	♂	Interstitial cystitis 14 years; capacity 120 cc.	Resection of presacral nerve	7	Frequency and some urinary discomfort but none of the old excruciating pain; bladder can hold up to 250 cc.; general condition much improved
33	♀	Residue of tuberculous cystitis 5 years; capacity 200 cc.	Resection of presacral nerve	6	Marked relief of pain; only slight relief of frequency
57	♀	Inoperable carcinoma of bladder; 5 weeks	Resection of presacral nerve	3	Satisfactory relief of pain
32	♂	Painful posterior urethritis and trigonitis 18 years; capacity normal	Resection of presacral nerve	6	Complete relief of pain; slight diminution in frequency
29	♂	Interstitial cystitis 7 years; capacity 90 cc.	Resection of presacral nerve; division of sacral rami communicantes and lateral sympathetic chains	5	Relief of vesical pain; still has burning in urethra; frequency being reduced by overdistention
52	♂	Chronic posterior urethritis and cystitis after prostatectomy 2 years; capacity normal	Resection of presacral nerve; division of sacral rami communicantes and lateral sympathetic chains	3	Little if any relief of pain or frequency
39	♀	Interstitial cystitis 1½ years; capacity 280 cc.	Resection of presacral nerve; division of sacral rami communicantes and lateral sympathetic chains	1½	Pain relieved; frequency much less
58	♀	Interstitial cystitis 10 years; capacity 100 cc.	Resection of presacral nerve; division of sacral rami communicantes and lateral sympathetic chains	1	Pain relieved; frequency appreciably less

* In this column, ♂ denotes male; ♀, female.

Spasm of the Neck of the Bladder.—I have divided the presacral nerve in two cases, in which failure to empty the bladder seemed to be due either to hypertonus of the internal sphincter or to incoordination of the nervous mechanism which secures relaxation of this structure at the beginning of micturition. The operation seemed logical, because relaxation of the internal sphincter after sympathetic neurectomy had been observed repeatedly. In each case residual urine was present, although there was no demonstrable reduction in the expulsive power of the musculature of the bladder. I feel that the operation has been worth while in both cases.

The most gratifying result was obtained in the case of a man, aged 58, who for ten years had had increasing difficulty in starting the flow of urine. At first this could be accomplished by straining, as a result of which bilateral hernias developed. Finally he could urinate only after introducing a small quantity of hot water into the rectum. He himself was convinced that difficulty in relaxing the sphincter was the cause of his condition, and cystoscopic examination failed to disclose any organic obstruction at the neck of the bladder. Various local operations had been performed elsewhere, without affording him any relief. The result of the operation was immediate; even in bed he did not have any difficulty in urinating, and he felt that the "spasm" of which he complained had been relieved. In the second case, the patient had complicating factors in diverticula into which the ureters opened. The residual urine amounted to 150 cc. and could be passed only with much straining. After operation the amount of residual urine was reduced, but 50 cc. was still present. Cystoscopy showed that the internal sphincter had regained some tonus, whereas the trigon and the posterior urethra remained relaxed. Suprapubic exploration was performed, but it was thought advisable not to resect the diverticula, as this would have involved an extensive reconstruction with reimplantation of both ureters. During his convalescence from the second operation, the posterior part of the internal sphincter was divided with a Colling knife. When normal micturition was reestablished, it was found that the patient emptied the bladder completely. This combination of neurectomy and local operation seems desirable in cases of this type.

Vesical Pain.—For some time it has been known that the thoracicolumbar autonomic nerves which are distributed to the bladder contain afferent fibers which communicate sensations of overdistention to the spinal cord. In a study of the behavior of the bladder following gunshot wounds of the spinal cord, Head and Riddoch had pointed out that when the level of the injury was such that this pathway alone connected the bladder with intact segments of the spinal cord, the patient could appreciate distention of the bladder.[5] My own observations on the effect of handling or stimulating the presacral nerves of patients under spinal anesthesia confirm this; in particular, in one case the patient stated that handling the presacral nerve with forceps was attended by a "crushing pain in the bladder." The first to apply this physiologic fact to the treatment of vesical pain was Pieri; several similar reports have appeared in continental literature. In order to include all the possible paths by which fibers of the thoracicolumbar outflow conveying impulses of pain might reach the central nervous system, Pieri[6] in a subsequent paper advocated, in addition to section of the presacral nerve, bilateral sections of the rami communicantes passing from the sympathetic chains to the first, second and third sacral nerves, and bilateral division of the chains themselves at the level of the fifth lumbar vertebra. The anatomic features of this operation are shown diagrammatically in figure 2. I have performed sympathetic neurectomy in eleven cases of vesical pain in which urologic measures had failed to secure lasting relief. The essential details of these cases are shown in the accompanying table.

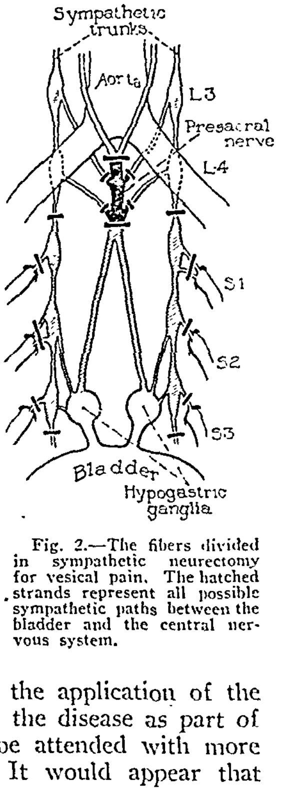

Fig. 2.—The fibers divided in sympathetic neurectomy for vesical pain. The hatched strands represent all possible sympathetic paths between the bladder and the central nervous system.

In six of these eleven cases, operation has been worth while. It seems to relieve the pain of spasmodic contraction of the bladder but has had little if any effect on urethral irritation. Frequency is not as a rule reduced, but after operation this symptom can be more effectively dealt with by overdistention of the bladder. As yet I have been unable to recognize the factors that make for success in some cases and failure in others. All the patients had been ill for long periods, and it is possible that the application of the operation at an earlier stage in the disease as part of the urologic treatment would be attended with more uniformly successful results. It would appear that when the operation is offered to patients with long standing disease, only about 50 per cent chance of relief can be given. Continental observers rate its efficacy higher, but my experience does not corroborate this optimism.

SUMMARY

A review of the nerve supply to the bladder is given.

The method of exposing the sympathetic nerves to the bladder is described.

Sympathetic neurectomy is indicated in cases of vesical paralysis, in which the lesion is situated in the parasympathetic pathway, and the sympathetic pathway is intact. The patient must be continent, and renal function satisfactory.

Sympathetic neurectomy, alone or combined with a local procedure, has proved efficacious in dealing with spasmodic conditions of the neck of the bladder.

Sympathetic neurectomy will relieve pain due to painful contractions of the bladder in about 50 per cent of cases; it does not directly relieve frequency.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. MILLER AND LEARMONTH

Dr. Alexander Randall, Philadelphia: Dr. Learmonth's presentation has many novel features. In 1912, Dr. William G. Spiller of the department of neurology of the University of Pennsylvania first conceived the idea of surgery to relieve pain. His idea was sectioning of the anterolateral columns of the spinal cord, and soon thereafter Dr. Charles H. Frazier did the first operation. In the subsequent years he has now performed this operation of chordotomy in over seventy cases. These have usually been performed for incurable malignant tumors, and it has been a brilliant surgical procedure. Done under local anesthesia, a delicate cutting of the sensory columns of the spinal cord is accomplished and at the same time there is a constant control by the testing of the anesthesia on the patient. Dr. Learmonth has gone further and included the control of the intractable conditions of the bladder as well as the pain from malignant tumors. It is impossible to say where the work will lead. The operation is one that necessitates the utmost dexterity. Any one who has seen it knows that its success depends on its completeness, and the completeness is one of delicate handling of small nerves. I wish to ask Dr. Learmonth what the rapidity of regeneration is. Sympathetic fibers can regenerate rapidly, and if one does such a neurectomy and then is faced with recurrence in a short time from regeneration one would question its value. That leads to a second question: How often will neurectomy be done as a treatment of symptoms and not as a cure of the cause? I fear that in many cases it will be done to relieve the effect and not be aimed immediately at the basic, fundamental pathologic process.

Dr. H. W. Plaggemeyer, Detroit: Dr. Learmonth's idea evidently is that, with a partial dysfunction of the parasympathetic or accelerator mechanism, removal of the sympathetic inhibitors enables the parasympathetics to function better or more nearly toward their normal. From previous experience in long-delayed recovery following certain cases of transverse myelitis in the army (without anything having been done), I am led to ask whether removal of the presacral sympathetic ganglion has permanent effect. We know from Lee's work on degeneration and regeneration that these sympathetic fibers often do not regenerate until after four or five months; in some cases, however, they regenerate in eight weeks. In this type of operation one must consider this, as these fibers do not have very far to go in order to end in the sympathetic ganglions in which they form synapses. I feel that we still have many more observations to make before we are sure of the total end-effect of the combined action of the hypogastric and of the pudic nerves. Although we have not tried it, it may be worth while, in necropsy material, to expose particularly the hypogastric nerves and stimulate them in the presence of the distended bladder soon after death. The bladder can function automatically after its nerves have been severed from the spinal cord. In cases in which the lesion is above the conus, the possibilities for automatism with reflexes taking place through the spinal cord are found. If the conus is destroyed, automatism even in such cases does take place and has been described by several authors. I should think with Dr. Learmonth that, in cases with complete transverse myelitis above the level of the conus and in which the vesical centers of the spinal cord are still in good connection with the bladder, if it is true that the hypogastric nerves are inhibitors their removal, partial or otherwise, might decrease the residual urine. If it is true that automatism can be established on a neurogenic basis in cases of complete transverse myelitis, which fact is accepted, why could not removal of the so-called inhibitors of the bladder enable the latter to function even better? Why does Dr. Learmonth consider complete transverse myelitis a contraindication? How long does it take for the residual urine to disappear following operation in cases of this classification? If long enough, may it not be true that the reeducation of the bladder may be responsible for some of the results obtained? If patients are operated on soon after injury to the spinal cord or to the parasympathetic nerves, the result may possibly be confused with what usually would have taken place without an operation. Dr. Learmonth has opened up a wide field of practical research.

Dr. R. W. Barnes, Los Angeles: Dr. Learmonth's paper has added to our knowledge of the treatment of the neurogenic bladder, but the method of treatment is not available to all of us. About a year ago I reported some results from the use of the sinusoidal galvanic current in treating these neurogenic bladders. It is known that some patients do not have residual urine but do have a high incontinence, and some have just the reverse. If one can obtain a balance of tone it will help these patients. In my service at the Los Angeles County Farm, where about 250 cases of bladder disturbances are under treatment, most of which are neurogenic, we have tried the sinusoidal or Morse wave current. In patients with residual urine and no incontinence, we use the active electrode on the suprapubic region to stimulate the bladder musculature, and for those with little or no residual urine we use the active electrode on the perineum, with the inactive electrode on the dorsal region. We have found that by balancing these two muscle forces in this way we can improve the status of these patients, reducing their residual urine some 75 per cent, decreasing the incontinence, and making them much more comfortable. It does not offer a method of cure, but it does help the patient and makes his life more livable.

Dr. W. F. Braasch, Rochester, Minn.: I have observed most of the patients whom Dr. Learmonth has operated on and can confirm what he said about the value of this work. Resection of the presacral nerve is particularly applicable to the group in which the lesion involves the terminal nerve supply rather than the central nervous system. I wish to refer briefly to the cystoscopic data observed in these cases subsequent to operation. These consist usually of diminution in sensation of the bladder mucosa, diminution in heat and cold sensation, dilatation of the blood vessels, and relaxation of the trigon. Subsequently the sensation may return to a greater or less extent, and the trabeculation which may have been previously present is usually found to be reduced or absent. As a rule, relaxation of the trigon and of the sphincter will persist. The infection in the bladder is often improved, apparently as a result of the increased blood supply and reduction in spasmodic contraction. We always employ the usual methods of local treatment of the bladder with interstitial cystitis before we resort to neurectomy, including overdistention, application of silver nitrate, and fulguration. In advising neurectomy for intractable cases we offer the patient only a 50 per cent probability of amelioration of symptoms and recovery. However, the relief from pain and dysuria is often so remarkable that the operation is indeed worthy of consideration in the treatment of these otherwise incurable patients.

Dr. Elmer Hess, Erie, Pa.: Renal sympathectomy is a symptomatic sort of procedure. My interest in it primarily has been in the control of pain, and in that way it does work. If there is regeneration of these nerves some time after the operation has been performed (and I am sure there is), I believe that one of the reasons why the patient does not continue to have pain is that the habit has been broken, as the result of the breaking of the nerve supply. There is a lot to be learned about sympathectomy. One should not rush blindly into an operation of this character, and I wish to emphasize the remarks of Dr. Braasch about trying something else first. I think that is exactly what one should do, but, after one has tried something else and the patients continue to be miserable, one is justified in using anything that will give symptomatic relief, even though one does not touch the pathologic condition.

Dr. H. Dawson Furniss, New York: I think the statement that these women are very miserable was not overemphasized. I have operated on thirty with the second type of incontinence that was mentioned and in 85 per cent have secured satisfactory results, with the other 15 per cent improved. The operation I have done most frequently was the first one Dr. Miller discussed (the Kelly procedure) in which one puckers the sphincter; in addition, I think one should pucker a good deal of the urethra itself, as it helps control. I have used a method very similar to the Kelly procedure, done suprapubically, when the typical Kelly method was not practical. One thing that must be remembered is that illustrations always make these things appear very much easier than they are. For tightening of the suprapubic sphincter, the patient must be well relaxed and must be in the exaggerated Trendelenburg position. The light must be good, for the sphincter is quite deep. The sphincter is not such a definite structure that one can locate it by touch. One must have a Pezzer catheter in place to locate the internal urethral orifice. In the much more relaxed cases I put in a second row of sutures. To place them, Young's boomerang needle holder is helpful. There may be some venous bleeding, but it is readily controlled by pressure. In some cases there is a prolapse, and in those I have added a stitch to hold the urethra up under the symphysis. I think it would be easier to encircle the urethra with the rectus fascia by passing it around the urethra suprapubically rather than infrapubically, and that it would be well to cross it in such a manner that fascia from the left side of the wound would go under the urethra from the right side and be joined above the urethra by fascia similarly passed from the right.

Dr. J. R. Learmonth, Rochester, Minn.: While it is undoubtedly true that sympathetic nerves regenerate, so long a segment of nerve has been removed in these operations that it seems to me out of the question that central fibers could reestablish communications with appropriate peripheral fibers. Moreover, the duration of the cures seems to be conclusive proof that such connections have not been reestablished. It is to be remembered that the portion of nerve removed contains both preganglionic and postganglionic fibers. In my opinion, the pudic nerve has less to do with the control of micturition than has been supposed. The intolerable itching of kraurosis vulvae may be relieved by bilateral section of the internal pudic nerve, without fear of subsequent incontinence. As has been emphasized by other speakers, the cooperation of Dr. Braasch and his colleagues has been very important. In some cases the operation is symptomatic, and it is then advised as an adjunct to urologic treatment. In certain cases of paralysis it seems to be curative, and the selection of suitable cases devolves on the urologist and the neurologist. I should be unwilling to carry out the operation in cases of transverse myelitis, in which, with good urologic care, satisfactory automatic emptying of the bladder develops in a large proportion of cases. Laparotomy does not seem to me justifiable in cases of this type.

The Disease Picture.—The reaction of the body to disease is directed to the restoration or approximation of the wholeness of health, by destruction of the invading parasite, through satisfactory readjustment to a permanent injury or by temporary accommodation to a physiological disturbance. Each individual attacks his problem, both consciously and unconsciously, in a different manner; and though the common problems themselves are fairly limited in number and more or less familiar to us, each patient's method of attack or of resistance, which we call the disease picture, is marvelously and infinitely varied. This matter of attack or of resistance depends on a multitude of factors; race, inheritance, age, environment, experience, education all come into play; and as these factors work to differentiate one person from another, so they tend to individualize disease in each single patient. The intricate combinations, in any man, of anatomical, physiological, immunological and psychological attributes, so aptly termed by Draper the "panels of personality," together form the fertile, indifferent or resistant soil on which the noxious germ is sown or injury done. The disease picture, the pathological state, depends on the manner in which these forces overcome this noxious agent, resist it, or sink before the fatal injury.—Longcope, W. T.: Methods and Medicine, *Bull. Johns Hopkins Hosp.* **50**:4 (Jan.) 1932.

Clinical Notes, Suggestions and New Instruments

ERB'S PALSY IN AN ADULT TREATED BY REATTACHMENT OF CAPSULE OF HEAD OF HUMERUS (METHOD OF KLEINBERG)

Maurice H. Herzmark, M.D., New York

History.—A. S., a man, aged 24, white, consulted me, March 17, 1930, because of a deformity of the left shoulder which made it impossible for him to bring his left hand to his mouth.

He stated that he was the youngest of eleven children and was born after a difficult and protracted labor. Shortly after birth it was found that his left arm was limp, and the attending physician strapped it to his side. Later the arm regained some power but became rotated inwardly. No attempt was made to correct the deformity until the age of 16 years. Several surgeons were consulted who advised operative correction. The parents refused consent to any operation, and the deformity continued unchecked. At the age of 21, after consultation with several orthopedic surgeons, the patient was advised that the deformity could be corrected only through an arthrodesis of the left shoulder joint. This he would not permit, and the matter rested until he came under my observation.

Examination.—The patient was well developed and in excellent condition. The left shoulder was somewhat lower than the right, and the muscles about it appeared much smaller than those on the right side. The line from the root of the neck to the point of the shoulder was convex on the left side, while on the right it was slightly concave. The pectoral muscles, deltoid and biceps were markedly underdeveloped on the left, while on the right these muscles appeared better developed than usual. The left upper limb was held habitually in marked inward rotation, with the elbow flexed at an angle of 135 degrees. Although the left shoulder appeared lower, the left elbow was on a higher level than the right. Posteriorly, it was seen that the left scapula was smaller than the right, and the head of the humerus was subluxated. External rotation was greatly restricted, the patient being unable to bring the point of the elbow against the side of the body. Flexion at the elbow was possible to normal range but extension was checked at about 140 degrees. Abduction of the left arm was purely scapular, the deltoid muscle taking very little part. The patient could not bring the left hand to his mouth; he could not touch the right shoulder; he could not bring his two palms together, except in a very awkward and ineffectual manner. Complete elevation of the left limb above the head was accomplished by a flipping motion. There was no demonstrable paralysis of any muscles, but the deltoid was extremely weak and lay posterior to rather than over the lateral aspect of the joint.

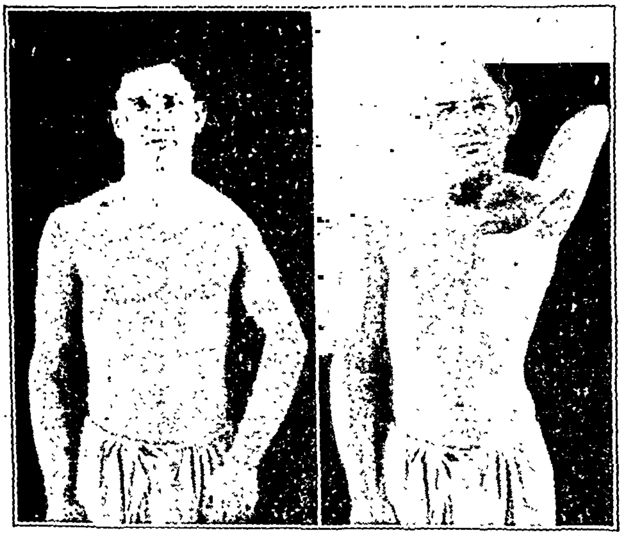

Fig. 1.—Before treatment. Deformity of shoulder: the patient is unable to reach mouth with left hand.

The diagnosis was Erb's palsy, with posterior dislocation of the head of the left humerus.

Treatment.—It was considered advisable to reduce the dislocation before attempting correction of the deformity. March 21, 1930, under a general anesthetic, the left upper extremity was manipulated so as to bring the head of the humerus into the glenoid fossa. This was accomplished by rotating the arm outwardly, at the same time extending it and forcing the head downward and forward. Reduction was accomplished without unusual effort, and, to insure maintenance of position, a plaster-of-paris shoulder spica was applied, holding the left arm rotated outwardly, extended, abducted to 90 degrees and the elbow flexed so that the palm of the hand faced the side of the body.

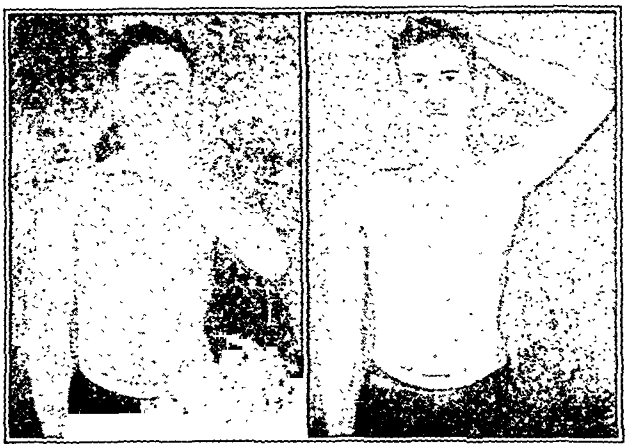

Fig. 2.—Five months after treatment. The patient appears less deformed. Motion about shoulder allows bringing of the left hand to mouth and top of head.

Two weeks later, April 4, the spica was removed. Examination of the shoulder showed that the head of the humerus was in position in the glenoid fossa. This position was maintained as long as the arm was extended and rotated outwardly, but as soon as flexion and inward rotation was permitted, subluxation resulted.

For the purpose of correcting the deformity, an open operation was done. The procedure followed was that of reattachment of the capsule around the head of the humerus, using the technic devised by Dr. Kleinberg.

An incision was made from the tip of the acromion process along the lateral margin of the arm nearly to the insertion of the deltoid muscle. The fibers of the muscle were split and retracted. The periosteum was incised in a linear direction along the lateral margin of the humerus from just below the surgical neck downward for about 2 inches, and at the lower level the incision was carried transversely. With a periosteal elevator, the perisoteum and capsule were lifted from the bone. The lesser tuberosity with part of the subscapularis muscle was stripped; the stripping continued medially around the bone. The greater tuberosity with its supraspinatus tendon was cut through and lifted from the bone. The stripping was continued until the bone was free. The humerus was then rotated outwardly as far as possible, and in this position the capsule was reattached, the outer lip overlapping the inner lip about three-fourths inch. The wound was closed in layers, the skin with black silk. A plaster-of-paris shoulder spica was applied, holding the left arm in outward rotation, extension, abduction to 90 degrees, the forearm flexed at right angles, and the palm facing the side of the body.

The patient walked about in the plaster spica, which was allowed to remain in position until May 12, when the upper part was cut away so as to permit inspection of the wound. The sutures were removed and healing had taken place by first intention. The patient was now taught how to remove this upper shell of plaster and exercise the deltoid and biceps muscles. Baking and massage were now begun on the part exposed by removing the plaster shell.

June 23, the plaster was entirely removed and an abduction splint was applied so as to lessen abduction.

Physical therapy and exercises were continued for a month, and the patient obtained employment as a garage mechanic. He continued to work and from time to time was treated with physical therapy.

Examination, September 28, showed great improvement in the deformity. The left shoulder appeared to be in a very satisfactory condition. The inward rotation was no longer present, and the patient could use his left arm quite satisfactorily. The deltoid and biceps muscles had improved markedly, and there was some development to be noted in the pectoral muscles. The patient could bring his hand to his mouth, touch the right shoulder, bring the left hand to the top of the head, behind the neck, and even touch the right ear. He was able to approximate his palms in an effective manner for carrying or working, and lifted a heavy chair by way of demonstration. The left arm could be extended and raised above the head in a normal manner without resorting to a flipping motion as formerly. The flexion contracture at the elbow was also slightly improved, although no treatment of this had been attempted. From a bar above the head, the patient was able to raise himself, with the palms facing toward the body, to a position in which the chin was brought to rest on the bar. This was repeated several times.

H. A. Carter, Secretary.

ELECTROSURGERY

A BRIEF REVIEW OF ITS ADVENT AND SOME OF ITS USES

HOWARD A. KELLY, M.D.
AND
GRANT E. WARD, M.D.
BALTIMORE

Electrosurgery came on the surgical horizon about 1907 as an outcome of the epoch making experiments of d'Arsonval and Oudin. The present efficient form of electrosurgery in this country, and largely in the world, is due to William L. Clark of Philadelphia, who took it over in a crude state and brought it to the borders of perfection. Addenda have been largely due to technical developments by electrical specialists, responding to stated needs of surgeons.

De Keating Hart and Pozzi over twenty years ago used a long sparking current of high voltage and low amperage for the destruction of tumors, called fulguration. Edwin Beer [1] of New York took this up about 1908 and used it extensively in bladder tumors. The difficulty with this agent was a lack of penetration: Beer's work, however, was distinctly prophetic of all that has followed.

The demand for electrosurgery arose from imperfections in the established surgical technic, long accepted as inherent in operative methods and, therefore, hardly realized until the new agent and the acquired facility necessary to its skilful application appeared to remedy them.

The reproaches indicated have lain in the prolongation of operations due to the application of ligatures to stop hemorrhage; in the liability of conveying infection or of distributing it in the general course of many operations; in the fact that ligatures acting as foreign bodies may become foci of infection; in the deplorable manipulations of tissues; in the contamination of wounds and general messiness of handling malignant growths and chronic and subacute infections; in the limitations often imposed on our extirpative work by reason of the depth of the operation from the surface, particularly in the oral and nasal cavities, in neural surgery, and in rectal and sometimes in abdominal procedures; in the fact that any serious difficulty of ligation in sharp hemorrhage in a deep operation often precludes a satisfactory continuation to its completion; in the condition of tissues after recovery, which makes a desirable secondary operation objectionable; in shock arising from prolonged operation with attendant hemorrhage. Experience has shown that these objections are in a measure overcome by electrosurgery.

Electrosurgery as now used is the employment of a high frequency alternating electric current of about 1,000,000 to 2,000,000 or more oscillations per second for the destruction or excision of diseased tissues. The current voltage and amperage under perfect control ranges from a minute, almost invisible, spark up to a heavy flashing flame, causing a necrobiotic heat penetration to the depth of 1 cm. on all sides of the electrode. The current is applied by "active" electrodes of various shapes: needle, thin narrow blade, ball, curet, wire loop.

These currents are applied through a uniterminal or biterminal connection with the generating apparatus, affording either a desiccation or a dehydration of the tissues, an electrocoagulation, or, by molecular disintegration, a cleavage or cutting of tissues.

The cardinal virtues of electrosurgery lie in effective destruction in loco of tissues that it is desirable to eliminate. This manifestly includes all forms of malignancy. There is no handling of tissues because of the knife and fork type of operation, which is unequaled in cleanliness by the immediate complete sterilization of both bacterial and malignant infection.

Hemostasis is easily effected in severing vessels up to about 1 mm. in diameter either by the application of the coagulating electrode direct or by the intermediary of a well-pointed hemostatic clamp, isolating the vessel. Thus ligatures are avoided, and the risk of infection is lessened by reason of the reduction of the imported foreign material. The ability to check hemorrhage, keeping the fingers away from the wound, makes it possible to continue deep work in various parts of the body.

Another advantage is the extended use of local anesthesia, which reduces hospitalization by making a number of these patients ambulatory.

A notable achievement lies in the group of operations being undertaken, many of them until recently hardly possible, particularly extensive malignant growths of the jaw, oral cavity, antra, brain, breast, thyroid, and vulva, resulting in a great number of patients with open wounds which, being kept clean, heal rapidly without pain or toxemia and yield a soft, pliable scar. Tonsillectomies in patients presenting contraindications for ordinary surgical procedures, such as cardiac disease and advanced age, are now being performed electrosurgically by trained operators. The destruction of the tonsil is effected in several stages, by applying the current alternately first to one side and then to the other, at intervals of one or two weeks. Such patients are usually ambulatory. The pillars must be kept from adhering by scar tissue until all infection disappears, thus avoiding encapsulation of infectious material. The method is still considered to be applicable only in selected cases and by men especially trained both in electrotherapy and otolaryngology.

---

[1] Beer, Edwin: Removal of Neoplasms of the Urinary Bladder, J. A. M. A. 54:1768 (May 28) 1910.

Those unfamiliar with the intensity of the high frequency currents and their depth of penetration may easily strike destruction into deep-seated structures adjacent to the disease areas. Especially is this true of blood vessels (a carotid, for example) leading to and from the part or traversing neighboring tissues. To prevent hemorrhage at the operation or subsequently when the coagulum sloughs away, a ligation of tributary vessels is often advisable. While muscles (the pectoral, for example) are being incised, the faradic effect may be sufficient to cause muscular jerkings lively enough to throw the electrode against a neighboring large vessel. Severance of nerves often causes the same muscular contraction in the muscles supplied, with dangerous possibilities.

Another pitfall is that of undertreatment, particularly in the hands of an amateur. The extreme limits of the disease must always be estimated in malignant conditions and the destruction and the extirpation carried well out into the normal zone. The electrosurgical aspirant should first acquire a good general surgical training, adding later to his technic the use of the high frequency electric currents. A mere novice has no more right to exploit this new adjuvant than has the first year medical student to prescribe digitalis.

Various forms of apparatus have been developed through the years to such an extent that at present the market is replete with many new instruments, some of them only fairly satisfactory. Research jointly by surgeon and physicist, together with the competitive spirit of a group of able manufacturers continually improving their products, has accomplished much in developing a number of admirable, perfect instruments. Two general types are available: The one, dating from the original experiments of d'Arsonval and others, employs a transformer, a series of condensers, spark gaps and an Oudin coil as the source of power; the other, beginning with the discoveries of de Forest, employs one or more triode vacuum tubes as the generating factor. Each surgeon will learn to choose for himself, after thorough trial, the type best adapted to his needs. The better machines furnish a current readily available by the easy manipulation of a comprehensible switchboard or the ready change of electrodes.

The perfect generator should produce a smooth current without faradic effect, varying from the finest desiccation spark to heavy coagulation without much flashing or uncontrollable flame. Efficient coagulation by a blunt or ball electrode brought near to the tissues, with the minimal visible sparking, is another criterion of a perfect current. There ought not to be any fusion of coagulated tissues to the electrode, but to date no material is available out of which electrodes can be made which will not stick to the tissues, pulling some away when removed and risking tearing a vessel. In addition, the cutting current should be regulable from one severing tissue with only 0.1 mm. of destruction on each side to one coagulating 1 or 2 mm. in depth. The fine cutting current permits primary union; the heavier cutting current used in excising an extensive ulcerative malignant growth leaves in situ a dry sterile coagulum, which prevents any local recurrence or the dissemination of cells spilled from the ulcer. In the latter class, the local defects are so great that primary union is not anticipated and the coagulum becomes a desideratum. All these features, characterizing the perfect machine with the minimum number of controls, should be available at the operating table through a proper foot switch or by sterile connections for the operator's immediate control, without calling for an extra assistant.

At present, electrosurgical cutting and coagulation are accomplished by separate electrodes, usually of different shape, either necessitating two connections with the machine or an interchange of electrodes in a common handle attached by a single wire to the apparatus. In the latter instance an extra assistant is needed to switch from cutting to coagulating current or vice versa. Two wires, used to carry the current, form an awkward addendum at an already complicated operating table. In operating rooms, where inflammable anesthetics are used, surgeons are urged to secure apparatus of the best construction and to keep it in good repair, because open or static electric sparks may cause serious explosions.[2] As time passes, it is hoped that these and other technical problems will be simplified.

1418 Eutaw Place—101 West Read Street.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

The Council has authorized publication of the following reports.
W. A. Puckner, Secretary.

MYODINE, SUBIDIN AND SANGUIODIN NOT ACCEPTABLE FOR N. N. R.

On account of the exploitation of certain "water-soluble" tinctures of iodine, advertised to physicians to be less irritant than, and therefore superior to, the official preparations Compound Solution of Iodine (Lugol's Solution) and Tincture of Iodine, Torald Sollmann published a report of an investigation in which the properties of the official solutions were compared with those of the proprietary preparations (The Journal, Sept. 20, 1919, p. 899). It was found that the official preparations were actually somewhat less irritant to the skin than the secret or nonsecret "miscible tinctures"; that the more even spreading and more rapid coagulation of protein renders a simple alcoholic solution of iodine best for "disinfection" of the skin, and that the delayed protein precipitation by the U. S. P. tincture would probably render it somewhat superior for the disinfection of open wounds. The report concludes that "The secret and nonsecret 'water-soluble' tinctures do not appear to have any material advantages."

According to inquiries received by The Journal, there appears to be a recrudescence, or a continued vogue, of proprietary preparations advertised with claims similar to those made for the discredited "water-soluble" tinctures and having apparently similar composition.

Myodine, Subidin and Sanguiodin are stated to be products of the I-O-Dine Laboratories, Inc., Philadelphia, marketed by Eimer and Amend, New York, N. Y. They are claimed to be "proteinized" or "vegetized" iodine solutions, prepared by combining "crystal iodine . . . with seaweeds and vegetables which have an affinity for iodine, digested by a special process." Myodine is stated to contain ".43 to .44 free iodine and about .30 iodine in combination. 6 to 7% of alcohol is added to the finished product." In quantitative determinations on a market sample by the A. M. A. Chemical Laboratory, Myodine was found to contain 0.25 per cent of free iodine, or 58.1 per cent of the amount claimed. Subidin is stated to have ". . . about 2.7 of free iodine. Between 25 and 30% of alcohol is added."

---

[2] Death from Explosion of Anesthetic Gases, editorial, J. A. M. A. 98: 530 (Feb. 13) 1932.

In quantitative determinations on a market sample by the A. M. A. Chemical Laboratory, Subidin was found to contain 1.82 per cent of free iodine, or but 67.4 per cent of the amount claimed. According to an advertising booklet sent out by the firm, Sanguiodin contains "Alcohol (by weight) 5.38. Free Iodine 0.44%. Total Iodine 0.77. Water by difference 93.41." Quantitative determinations on a market sample by the A. M. A. Chemical Laboratory showed Sanguiodin to contain 0.05 per cent of free iodine, or but 11.4 per cent of the amount claimed. From this it is apparent that the preparations are essentially "water-soluble" iodine preparations of varying strengths marketed with indefinite and incorrect statements of composition.

The more recent advertising for Myodine and Subidin recommends these products for use in the mouth, throat and nose; circulars for Sanguiodin state that the preparation is for "Internal and Intramuscular Administration wherever Iodine is Indicated." Older circulars are not so modest about naming specific conditions with strong assertions of the value of the products in these; those for Sanguiodin recite a host of diseases with enthusiastic recommendations for the value of the product. The late circulars for Myodine and Subidin assert that these products are superior to the pharmacopeial preparations as being not "toxic" or "caustic" and generally therapeutically superior. The circular for Myodine is obviously addressed to the public.

The Council declared Myodine, Subidin and Sanguiodin unacceptable for New and Nonofficial Remedies because they are unscientific modifications of an official article marketed with unwarranted claims and indefinite and incorrect statements of composition under proprietary, uninforming names.

VEGE-SEA AND ORO BRAND KELP SALT NOT ACCEPTABLE FOR N. N. R.

"Vege-Sea" is stated by the Oakland Food Products Co., Oakland, Calif., the distributors, to be dried and powdered kelp while "Oro Brand Kelp Salt" is stated to be a flavored mixture of this kelp with ordinary salt.

According to the advertising, "Vege-Sea" is "The Ocean's Gift to the land," which is offered with the claim: "Adding a little VEGE-SEA to the every-day diet will relieve and prevent many illnesses and disorders by supplying necessary elements for the body." Vege-Sea and Oro Brand Kelp Salt are recommended to be used to add mineral constituents to the diet as a sort of general prophylaxis and as a source of iodine for goiter prophylaxis. Additional increase of marine mineral salts could only be of value if there were insufficiency of these special constituents in the diet—a condition which is probably very exceptional but which, if it exists, can be better corrected by supplying the special salts that may be deficient. As concerns goiter prophylaxis, it appears inadvisable to rely on the indefinite amounts of iodine which may be introduced in the form of kelp. The advertising aims to create the misleading impression that ordinary iodine preparations fail to prevent goiter; thus, it is claimed: "Soluble iodine is not necessarily assimilable iodine. In this connection it has been noted that the connection between goiter and iodine deficiency in the diet has been known for the last century yet little has been accomplished by the feeding of iodides. On the contrary it appears that goiter is on the increase. This fact is attributable to the fact that we are eating more and more highly refined foods and drinking more and more surface water."

The marketing of dried kelp or of a mixture of kelp and salt does not present any originality, and hence there is no warrant for the sale of these preparations under coined names.

The Council finds "Vege-Sea" and "Oro Brand Kelp Salt" unacceptable for New and Nonofficial Remedies because they are marketed with claims that are unwarranted and misleading and because the recognition of proprietary names for these unoriginal preparations is not in the interest of rational therapy.

Colles' Fracture.—Most Colles' fractures accompanied by fractures of the ulnar styloid have sufficient (96 per cent) displacements of the lower radial fragment to warrant reduction in order to obtain the best possible anatomic realinement which is usually essential for the best end-results.—Carp, Louis: *Arch. Surg.* **24**:1 (Jan.) 1932.

Committee on Foods

The following products have been accepted by the Committee on Foods of the American Medical Association following any necessary corrections of the labels and advertising to conform to the Rules and Regulations. These products are approved for advertising in the publications of the American Medical Association, and for general promulgation to the public. They will be included in the Book of Accepted Foods to be published by the American Medical Association.

Raymond Hertwig, Secretary.

ALICE OF OLD VINCENNES TOMATO JUICE

Manufacturer.—Vincennes Packing Corporation, Vincennes, Ind.

Description.—Pasteurized tomato juice with added salt; retains in high degree the vitamin content of the raw juice.

Manufacture.—Selected varieties of tomatoes raised in southern Indiana under contract are washed in tanks and inspected on moving belts. Only ripe tomatoes grading as No. 1, U. S. grade, are chosen for the manufacture of this brand of tomato juice. The tomatoes pass between two studded bronze rolls operating in opposite directions, are flattened and punctured, and fall into an enclosed stainless steel hopper connected to the juice extractor. The hopper and extractor are filled with steam vapor to eliminate air. The extractor is a bronze tube with openings of 0.004 inch diameter and is equipped with an internal heliocoid revolving at 60 revolutions per minute. The heliocoid is so constructed that one revolution at the intake moves the tomatoes eleven inches, which distance per revolution is gradually reduced toward the outlet, where one revolution produces a three inch movement; nine inches of punctured tomatoes are gradually squeezed into a three inch space, which expresses the juice. The light pressing tends to prevent extraction of the juice from the core, which is bitter. The expressed juice flows into a pan, which is the only place it is exposed to the air; it flows immediately to a glass lined tank, where it is heated to 62 C. A small amount of salt is added, after which it flows directly to the filling machines and is filled into glass bottles or tins, which are heated to 100 C. for about fifteen minutes. Precautions are taken throughout the processing to prevent contact with air wherever possible in order to protect the vitamin content.

Analysis (submitted by manufacturer).—

	per cent
Moisture	93.2
Ash	0.9
Salt in ash	0.5
Fat (ether extract)	0.3
Protein (N × 6.25)	1.1
Reducing sugars as invert	3.6
Sucrose	0.0
Crude fiber	0.1
Carbohydrates other than crude fiber (by difference)	4.0
Titratable acidity as citric acid	0.4
Phosphoric acid as P_2O_5	0.03
Citric acid	0.3
Malic acid	0.2

Calories.—0.3 per gram; 9 per ounce.

Micro-Organisms.—Culture tests indicate sterility.

Vitamins.—Vitamin A: Vitamin A starvation symptoms in rats are cured by 0.2 cc. of juice daily. Assuming the daily curative dose as representing one unit of vitamin A, then one can (300 cc.) has a potency of 1,500 A units, which approximates the A potency of a teaspoonful of a good grade (400 unit) cod liver oil.

Vitamin B (complex): Normal growth is restored to vitamin B (complex) starved rats by 10 cc. of juice. One can (300 cc.) is equivalent to approximately 36 Gm. of yeast cake (three cakes).

Vitamin C: Vitamin C starvation symptoms in guinea-pigs are cured by 2.5 cc. of juice daily, which indicates that most of the vitamin C of the raw juice is retained.

Claims of Manufacturer.—This tomato juice is a good source of vitamins A and B and an excellent source of vitamin C. It is suitable for infant feeding and for general table use.

"220" BREAD (KORN'S)

Manufacturer.—H. Korn Baking Company, Davenport, Iowa.

Description.—A white bread made by the sponge dough method.

Manufacture.—The sponge dough ingredients, 65 per cent patent flour of Southwest wheat and 70 per cent patent flour of Northwest wheat, water, yeast, and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate, are mixed in a high speed mixer. The sponge dough is fermented for from four to five hours, after which are added flour, water, salt, dextrose, lard and powdered skim milk to make the completed dough, which is cut into pieces of desired weight. The pieces are fermented for a short time, molded into loaf form, panned, further fermented, baked for from thirty to thirty-five minutes, cooled, and wrapped in wax-paper.

The factory, equipment and storage rooms are kept in strictly sanitary condition.

Analysis (submitted by manufacturer).—

	per cent
Moisture (entire loaf)	35.2
Ash	1.4
Fat (direct ether extraction method)	1.2
Protein (N × 6.25)	9.4
Crude fiber	0.2
Carbohydrates other than crude fiber (by difference)	52.6

Calories.—2.59 per gram; 73.6 per ounce.

Claims of Manufacturer.—A bread of good quality.

BORDEN'S OREGON, PEARL, ST. CHARLES, MARICOPA AND SILVER COW BRANDS EVAPORATED MILK

Manufacturer.—The Borden Company, New York.

Description.—Canned, unsweetened, sterilized, evaporated milk.

Manufacture.—Whole milk from healthy cows and produced under carefully supervised, sanitary conditions is used. All milk deliveries are tested for odor, flavor and sediment, and for acidity when necessary; a direct microscopic examination or the methylene blue "reductase test" is applied also.

Accepted milk is heated to 95-100 C., drawn into a "vacuum pan" and concentrated at 50-57 C. until about 60 per cent of the water is removed. The concentrated milk is homogenized by being forced under high pressure through small apertures, which disperses the fat into fine globules and prevents its separation during storage. The homogenized milk is cooled and tested to assure its conformity to the federal and state government standards for evaporated milk and is then automatically canned. The sealed cans are processed under steam pressure at 112-118 C. for from twenty to thirty minutes and chilled immediately thereafter. The product is examined after ten days' storage.

Analysis (submitted by manufacturer).—

	per cent
Total solids	26.0
Moisture	74.0
Ash	1.6
Fat	7.9
Protein (N × 6.38)	6.9
Lactose (by difference)	9.6

Calories.—1.4 per gram; 40 per ounce.

Claims of Manufacturer.—These brands of evaporated milk are suitable for general baking, cooking and table uses and in infant feeding. The mixture of equal parts of the evaporated milk and water is not below the legal standard for whole milk. The curds formed in the stomach are smaller, softer and more readily digestible than those from raw or pasteurized milk.

BORDEN'S PURE ORANGE JUICE

(Preserved by Freezing)

Manufacturer.—Borden's Farm Products Company, Inc., New York.

Description.—An unsweetened, uncolored frozen orange juice packed in hermetically sealed half pint paper containers.

Manufacture.—Florida tree-ripened oranges conforming to state sugar-acid ratio regulations are used immediately for the preparation of the juice or are stored in refrigerated rooms. The oranges are inspected, washed in a solution of calcium hypochlorite, mechanically scrubbed and sprayed with chlorine water, again inspected, conveyed to the inspection room, sprayed with chlorine water and conveyed to the extracting machines. The oranges are mechanically halved and each half is placed in a cup-shaped device, which descends on a knob-shaped head, which expresses the juice by displacement. The peel is so supported that practically no peel oil is expressed with the juice.

The expressed juice is collected, strained free of seeds and much of the pulp, further cooled in glass-lined tanks, and pumped through a tubular brine cooler which delivers the juice at approximately 1 C. The cooled juice is subjected to a "vacuum" (2 inches mercury pressure), then saturated with carbon dioxide gas and subjected to a second "vacuum" treatment. The first vacuum treatment removes much of the dissolved oxygen. The carbon dioxide "wash" removes the remaining oxygen and the second "vacuum" removes the carbon dioxide.

The air-free juice is conveyed to a glass-lined tank in which an atmosphere of carbon dioxide is maintained; the juice gravitates to seal-cone filler bowls also containing an atmosphere of carbon dioxide. Half pint seal-cones are filled with orange juice and for a few seconds only before the cones are sealed is the juice exposed to the air. Just previous to the sealing of the container, a puff of carbon dioxide is introduced to displace the air above the juice. The sealed containers suspended on an endless chain are conveyed through a freezing tunnel of calcium chloride brine maintained at —23 C. The frozen cone of orange juice is removed, packed in cartons, sealed, and stored at —17 C.

The extracting and filling rooms are closed and ventilated with filtered air. The frozen orange juice is shipped in refrigerated cars maintained at —6 C.

Analysis (submitted by manufacturer).—

	per cent
Moisture	89.5
Total solids	10.5
Ash	0.5
Fat	0.1
Protein (N × 6.25)	0.5
Crude fiber	0.02
Reducing sugar (as invert)	3.7
Sucrose (by copper reduction)	4.7
Total carbohydrates (by difference)	8.7
Titratable acidity as citric acid	0.9
Sugar-acid ratio	13.2: 1

Calories.—0.4 per gram; 11 per ounce.

Vitamins.—Biologic tests indicate that the vitamin C potency of this frozen orange juice is not demonstrably less than that of fresh orange juice.

Claims of Manufacturer.—A frozen orange juice nutritionally equivalent to fresh orange juice, packed in paper cartons for daily delivery to the final consumer. This frozen orange juice is suitable for all the uses of fresh orange juice.

WOLF'S BREAD

Manufacturer.—William Wolf's Bakery, Inc., Baton Rouge, La.

Description.—A white bread made by the sponge dough method.

Manufacture.—The sponge dough ingredients, 65 per cent patent flour of Southwest wheat, water, yeast and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate, are mixed in a high speed mixer. The sponge dough is fermented for from four to five hours, after which are added flour, water, salt, sucrose, lard, and sweetened condensed skim milk to make the completed dough, which is cut into pieces of desired weight. The pieces are fermented for a short time, molded into loaf form, panned, further fermented, baked for from thirty to thirty-five minutes, cooled, and wrapped in wax-papper.

The factory, equipment and storage rooms are kept in strictly sanitary condition.

Analysis (submitted by manufacturer).—

	per cent
Moisture (entire loaf)	34.0
Ash	1.0
Fat (direct ether extraction method)	0.9
Protein (N × 6.25)	9.3
Crude fiber	0.2
Carbohydrates other than crude fiber (by difference)	54.6

Calories.—2.6 per gram; 74 per ounce.

Claims of Manufacturer.—A bread of good quality.

THE SUPRARENAL CORTEX AND BODY TEMPERATURE

One of the features of investigation in physiology within the past two years has been the extensive study of the cortex of the suprarenal gland and its secretion. Recent investigations of the suprarenal structures have changed the emphasis that was placed only a few years ago on the respective functions of the different parts of the indispensable organ. The discovery of epinephrine in the medullary portion directed marked attention to the latter as a tissue of dominating significance in the body. It would be unfair to imply that the secretion of epinephrine is not of large physiologic moment. Many of the critical adjustments in the body, particularly in emergencies, are facilitated by this aspect of suprarenal response. Nevertheless, when considered in terms of absolute indispensability for life, the cortex of the suprarenal now must take first rank. Without the medulla, existence may still be assured; not so without the cortex. Loss of the latter is fatal. For this reason, replacement therapy with the recently described cortical extracts has quickly achieved prominence in clinical as well as in purely experimental fields. The studies out of which this enthusiasm has been developed have repeatedly been referred to in The Journal.[1] A common observation is the difficulty of regulating the body temperature of these animals; when they succumb soon after the operation there is a marked fall in body temperature and even surviving individuals in a warm room tend to have a subnormal temperature. Epinephrine is a recognized calorigenic agent and it is reasonable to expect that the loss of the main source of this hormone through suprarenalectomy would result in difficulty of maintenance of temperature. Indeed, there is evidence of an increased production of epinephrine in the normal animal after exposure to cold. However, a recent report from Hartman's[2] laboratory at the University of Buffalo describes experiments which indicate strongly that it is the lack of cortical tissue rather than that in the medulla of the suprarenal which is responsible for the failure to maintain a uniform body temperature after total suprarenalectomy. Apparently the processes of defense against cold are weakened.

Young albino rats were employed for these studies. After removal of the suprarenals one group was given subcutaneous injections of "cortin," the extract of the suprarenal cortex, and a second group isotonic sodium chloride solution. These together with a third group of intact normal animals were carefully observed for changes in body temperature at 27 C. There was little difference between the rats at this temperature. All the animals were then exposed to cold for three hours. At the end of this time the experimental group which had been treated with cortical extract had decreased 2 degrees in body temperature, whereas the similar group with saline solution only had lost approximately 10 degrees. The temperature of the normal animals changed little, if any, under this treatment. The normal rats became active and remained so during the exposure to cold; the cortin treated group was active during the early part of the cold period, but the untreated animals became quiet and lethargic. A similar experiment in which epinephrine was administered to one group of rats demonstrated the failure of this substance to enable the animals to maintain body temperature when exposed to cold.

The lack of adjustment to surrounding temperatures after removal of the suprarenals may be due to a decreased heat production or to an exaggerated loss of heat. Hartman and his co-workers determined the heat production in two groups of rats before and after suprarenalectomy and showed that one result of the operation was a distinctly lowered metabolic rate. However, when cortin was given following the removal of the glands, there was little change in heat production until sodium chloride solution replaced the cortical extract, when the energy metabolism fell. The effect of exposure to cold on the heat production was then studied. In normal individuals the metabolic rate early in the cold period was increased 54 per cent, whereas in the suprarenalectomized animals without cortin the increase was only 17 per cent. It thus appears that a large part of the difficulty of maintaining body temperature in the absence of the cortical hormone when exposed to cold is due to the failure to produce the added heat which is apparently a normal response in the intact animal.

These studies are particularly significant because they provide a promising method of assay for cortical hormone preparations, a lack of which has retarded progress in this field. Once the potency can be determined and expressed with reasonable accuracy, the way will be opened for further investigation of a quantitative nature. Furthermore, it appears possible to assume with greater assurance that the hormones of the medulla and the cortex are separate entities. And once again the biochemist has paved the way to further study of function by devising a method for the preparation of a potent tissue extract possessing a reasonable degree of specificity.

WATER AND HEALTH

A competent writer[1] on diet in disease has recently ventured to express the conviction that "the dietetic error that has killed more patients than any other is the neglect of administering enough water." He adds that in acute disease a highly colored urine is a reproach to the physician and the nurse; a dehydrated skin and tongue are danger signals. Few persons who deal with the functions of the living body, whether in health or in disease, realize that water constitutes more than 70 per cent of protoplasm, the structural basis of organic life. In health, water is not merely incidental in this connection—merely present as ballast or a reserve in the way in which fat may accumulate in the body. Water constitutes the medium in which the chemical changes of metabolism occur.[2] As water is continually lost to the body through various paths, by way of the kidneys, bowels, lungs and skin, it is obvious that the output must be adequately replaced if a healthy "balance" is to be maintained. This means that the intelligent practitioner should have some conception of the magnitude of the factors involved in the daily exchange.

The relative output by the various channels differs widely in different persons and in the same person under unlike conditions. An undue intake of fluid, for example, may be followed by a compensatory output. Augmented heat production in the body, as the result of exercise or perchance of fever, calls for water to facilitate the dissipation of the heat so that the normal temperature of the body will be conserved. The insensible perspiration of healthy adult persons during periods of quiet in an ordinary atmospheric environment is not less than an ounce (30 Gm.) during an hour; this means more than 700 cc. a day eliminated in ways that are not directly recognized. According to Flack and Hill, as much as 10 liters of water may be evaporated during a ride in the sun in the southern California desert. The variations in urinary output are familiar. The average sized man is transporting nearly a hundred pounds of water in his body, which consists of this substance to the extent of about two thirds of his weight.

How are the recurrent losses already referred to made good from time to time? Atwater and Benedict found variations in consumption of water ranging from an average of 2,290 cc. for persons in repose to 3,700 cc. for those at moderate work. In addition to this, the transformation of foodstuffs in metabolism leads to the production of considerable water from the oxidation of hydrogen. Sugar produces half its weight of water. These are endogenous sources. What is not generally recognized, however, is the large contribution of water made by almost all the foods that we eat. Few of them yield less than half of their weight as water; most of them considerably more. More than nine tenths of many fruits and vegetables consist of water. In an ordinary diet, as much as a quart of water a day may be taken in the form of so-called solid foods. A person in repose will take into his body a total of about 5 quarts of water every day, 2 quarts in the form of drink and 3 quarts in the form of foods. To many it is thus a surprising fact that when we eat food we almost invariably are unwittingly consuming water. Consequently, Du Bois[1] has pointed out that when for any reason solid foods are cut off in disease it is necessary to supply a proportional increase in the liquid foods in order to bring the water intake up to the level of that of an ordinary person in health. In acute disease, a still further increase in water intake should be made in order to compensate for the excessive loss through the skin and lungs.

DERMAL ABSORPTION OF SALICYLATES

Salicyl esters such as methyl salicylate (oil of wintergreen) are commonly prescribed as constituents of ointments, liniments and local applications, on the assumption that they possess a greater skin penetration, owing to their lipoid solubility, than do other salicylates. The amount of salicyl absorbed under these conditions would appear nevertheless to be too small for definite systemic effects. More important than the systemic actions from local applications of such products is the information they may yield regarding dermal function. The effects on the skin as determined by the properties of the constituents and of the vehicles of the mixtures merit attention.

As a group of relatively simple chemical substances, the salicyl compounds offer a good opportunity for testing the comparative importance of lipoid and water solubility, and of the chemical reaction (basicity and acidity) in dermal absorption. Lipoid solubility has generally claimed a larger share of importance for dermal penetration and absorption of substances than other properties, owing to the fatty nature of the skin as a membrane. However, the recent observations of Kionka[1] of the Jena Pharmacologic Institute on the dermal absorption of different salicyl compounds indicate that lipoid solubility may not be as important as some other factors. Clinically, the reactions of the skin are capricious.

Using the shaved skin of rabbits, Kionka determined the absorption of sodium salicylate, salicylic acid, acetylsalicylic acid, and the salicyl esters and certain of these products in the presence of camphor, capsicum and other irritants. The skin areas were 120 square centimeters, to which 5 Gm. of an ointment containing the salicylate were gently applied with the fingers for exactly two minutes. The dermal absorption was indicated by the appearance of salicyl in the urine, and the efficiency of penetration by the smallest amount of the preparation, when applied to the skin, that would give a positive test for salicyl in the urine. Salicylic acid (lipoid soluble) and sodium salicylate (water soluble) were absorbed with about equal readiness, contrary to current suppositions, which would ascribe little or no penetration to water soluble agents. Acetylsalicylic acid (lipoid soluble and rather acid) was the most readily absorbed, that is, once again as fast as sodium salicylate, and faster than that when compared with salicylic acid. The lipoid soluble methyl, salicyl and bornyl esters and salicylamide, however, were only about one third or one fifth as absorbable as acetylsalicylic acid, and about one half as compared with sodium salicylate and salicylic acid. These were the results obtained with the salicyl compounds in comparatively indifferent bases, such as a mixture of petrolatum and olive oil or hydrous wool fat.

---

[1] Kionka, H.: Klin. Wchnschr. 10: 1570 (Aug. 22) 1931.

The absorption of acetylsalicylic acid, sodium salicylate and salicylic acid was materially increased (about 30 per cent) when applied in the same vehicles containing 1 per cent of sodium carbonate, 0.27 per cent of extract of capsicum, or 2 per cent of camphor. The absorption of the ester methyl salicylate, under these conditions, was not enhanced. Camphor was rather efficient for improving the absorption of salicyl salicylate, which was increased 70 per cent. The increased absorption from the carbonate ointment was attributed to the skin-softening effects of the increased alkalinity, which probably was responsible for the absorbability of the water soluble sodium salicylate. Absorption was not facilitated by the addition of ammonia liniment (also alkaline) to the ointment, but here the soap formation may have acted as a colloid protective barrier to absorption. The irritants camphor and capsicum were superior to the sodium carbonate, in promoting absorption; their efficiency was due to hyperemia.

Moderate degrees of chemical reaction, i. e., basicity and acidity, possessed by substances, appear to be more important than lipoid solubility for penetration of the skin. Alkalinity, which softens the skin, and acidity, which apparently hardens it, are more important than simple solution in the fatty secretion of the skin. Dermal penetration and absorption are as much a function of changes in skin tissues as solubility in its fatty excrescence. The latter undoubtedly assists in bringing lipoid soluble agents into intimate contact with the skin and its circulation, but, without some structural and local circulatory changes in the skin tissue proper, simple contact with capillaries is insufficient for satisfactory penetration.

Current Comment

THE HEART AS AN ELECTRICAL GENERATOR

The power of the human heart as a pump is marvelous. If the output of the hearts of the inhabitants of the United States were combined, the total energy would approximate 70,000 horse power, delivering each day nearly the equivalent of the flow of the Niagara River. The output of the human heart as an electrical generator is, however, exceedingly small. Bush and Reid [1] say that if the maximum of the mean electrical power of the heart should be applied for lighting purposes it would be capable of giving only a one second illumination of a small flashlight bulb once in a thousand years. The accurate measurement of the variations of this small amount of electrical energy became possible in 1903 when Einthoven introduced the string galvanometer. Since then the electrocardiograph has been an instrument prominent in cardiac research and valuable in the diagnosis and prognosis of heart disease. The string galvanometer, however, was found to have serious limitations, so the measurement of minute electrical magnitudes has advanced since Einthoven's work. The introduction of the thermionic tube has revolutionized the technic of fine electrical measurement. As an oscillator, the thermionic tube can repeat a predetermined performance a hundred million times in a second. To operate a tube recently introduced, the input current necessary in comparison with the full ampere necessary to operate a moderate size incandescent lamp is small, so small that if the single ampere in the lamp should be represented by all the women of this country talking in unison at the rate of 150 words a minute, the grid current of this tube would be represented by a lone mountaineer who speaks one monosyllable in thirty years. While electrocardiographs using thermionic amplifiers in conjunction with oscillographs have been designed, they have been used chiefly to duplicate the results given by the string galvanometer. Now the Massachusetts Institute of Technology, in cooperation with the Evans Memorial Hospital, has produced an instrument which, although as yet only a research tool, has accomplished new things. It has brought out detail that was lost in the older records; it has produced an enlarged record with a relatively fine line; and by requiring a negligible current for its operation, it has avoided errors due to the flow of current through the variable impediment of the skin. The new instrument gives the sensation that one can study under the high power of the microscope, as it were, what formerly could be viewed only under the low power. Time will tell what new information may be obtained with this improvement after many patients have been examined and many clinical and postmortem reports have been correlated. The design of the clinical electrocardiograph will probably change ultimately in the direction of the new instrument. The result should be a further disclosure of knowledge of the normal and the diseased heart.

THE INNERVATION OF THE LIVER

The growing recognition of the varied rôles that may be assumed by chemical stimulants—hormones—in the organism has tended to deprive some of the branches of the nervous system of the functional dominance with which they were endowed in the physiology of earlier days. The classic studies on the actions of the nerves of the heart and of the salivary glands, for example, afforded full justification for the glorification of the dignity of nerve influences in fundamentally important life processes. Meanwhile the evidences for the comparable importance of humoral, in contrast with nervous, influences in various functional processes are gaining in number. Some may surprise readers who find satisfaction in resigning important physiologic responses to the nervous system alone. Notable are a series of observations recently made at the Mayo Foundation on some of the responses of the liver in the absence of all sympathetic innervation.[1] The nerve supply to the liver is generous, so that one might logically assume it to be of large physiologic importance. Yet, in the experiments of Lundberg, denervation of the liver did not produce a constant effect either on the amount of bile secreted or on the amount of pigment eliminated. Hillyard made a study to determine whether the increase in secretion of bile that follows the ingestion of food is dependent on the hepatic nerves. It was found that a mixed meal caused the greatest increase of biliary secretion, a protein meal caused a marked increase, a fat meal usually caused a moderate increase, occasionally there was neither increase nor decrease, and a carbohydrate meal gave variable results, either an increase or a slight decrease, or the output remained the same. After the hepatic nerves of both the sympathetic and the parasympathetic systems had been sectioned, fasting, feeding and collections were carried out as before, and it was noted that each of the foregoing test meals produced about the same increase in biliary secretion as before denervation. Evidently the increase in biliary secretion after the ingestion of food is not dependent on the nerves to the liver. Donald observed that denervation of the liver did not affect the value for fasting blood sugar, the hyperglycemia produced by epinephrine, dextrose and pituitary extracts, or the hypoglycemia produced by insulin. Accordingly, this study would seem to indicate that the regulation of the value for blood sugar does not depend on an intact nerve supply to the liver. Reasoning that the nerves to the liver are apparently vasomotor in function and that they would be factors in the control of certain constituents and processes in relation to the blood and to circulation, Hill studied the effects of denervation of the liver on the formed elements of the blood. The number of erythrocytes, the number of leukocytes, and the coagulation time of the blood remained unmodified. Thus has the largest glandular organ of the body been relieved of the supposed dominance of its nervous regulators.

THE NEW ORLEANS SESSION

Invitation to Members of Section on Dermatology and Syphilology to Visit Leprosarium

Dr. O. E. Denney, medical officer in charge, extends an invitation to the members of the Section on Dermatology and Syphilology of the American Medical Association to visit the National Leprosarium at Carville, La., on Tuesday, May 10. The institution is about 90 miles from New Orleans, and it is planned to have busses leaving the Roosevelt Hotel at 9 a. m.

Some 360 cases at the institution will permit the demonstration of many types of leprosy in different stages of advancement. Lunch will be served at the hospital, and on the way back to New Orleans a stop will be made to permit a visit to one of the old plantation houses.

Section members desiring to take advantage of this opportunity are asked to write either to Dr. Ralph Hopkins, Pere Marquette Building, New Orleans, or to the secretary of the section, Dr. Francis E. Senear, 55 East Washington Street, Chicago.

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Monday from 12 noon to 12:05 p. m. over Station WBBM (770 kilocycles, or 389.4 meters) and other stations of the Columbia Broadcasting System, and on Wednesday and Friday from 2:25 to 2:30 p. m., over Station WBBM, Chicago.

The program for the week is as follows:

February 22.	Compensations.
February 24.	Twelve Points in Noise Abatement.
February 26.	Whom Shall I Consult?

There is also a fifteen minute health talk sponsored by the Association on Saturday morning from 11:15 to 11:30.

The program for the week is as follows:

February 27.	Food for Children from Two to Six.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

Personal.—Dr. Charles W. Decker succeeded Dr. George Parrish as health officer of Los Angeles, Nov. 1, 1931.——Dr. David M. Kindopp, Colfax, has been appointed health officer of Placer County to succeed Dr. Theodore Snypp, Auburn.——Dr. Elwin F. Reamer, Modesto, has been appointed health officer of Stanislaus County, succeeding the late Dr. Orion I. Bemis, Riverbank.——Dr. Carl F. Larson has succeeded Dr. Charna G. Perry as health officer of Sausalito.——Dr. Burt S. Stevens, San Francisco, was recently appointed a member of the state board of medical examiners to succeed Dr. Henry A. L. Ryfkogel, whose term expired.

Graduate School of Nursing.—The San Francisco Department of Health established a graduate school of nursing, January 1, at the San Francisco Hospital School of Nursing. The institution had heretofore been conducted for undergraduates, and the decision changing its policy followed a careful analysis of costs of patient care as well as of the problems of nursing education. Advanced courses in children's diseases, maternity and operating room technic, tuberculosis and communicable diseases are now outlined with the development of special courses in ward administration, genito-urinary diseases and psychiatric nursing proposed for the near future.

Society News.—Dr. Willis C. Campbell, Memphis, Tenn., addressed the California Academy of Medicine, January 23; during his stay in California, he also spoke before the University of California and Stanford University, Oakland Surgical Society, St. Mary's Hospital Society and the San Francisco

---

M.: Studies on Carbohydrate Metabolism Following Denervation of the Liver, ibid., p. 605. Hill, F. C.: The Formed Elements of the Blood, Coagulation Time, Peptone Leukopenia After Section of the Nerves to the Liver, ibid., p. 610. Hillyard, L. V.: The Effect of Denervation of the Liver on Secretion of Bile, ibid., p. 612.

Dental Association. His subjects included the treatment of intracapsular fractures of the femur, arthroplasty of the knee, arthroplasty of the jaw, treatment of ununited fractures, and arthrodesis of the sacro-iliac joint.——A symposium on the liver was held before the Alameda County Medical Association, February 15, by Drs. Hugh G. MacLean, Robert A. Glenn, Safford A. Jelte and William W. Crane, Jr. Dr. John C. Meakins, Montreal, Canada, will conduct a clinic before the society at its meeting in March.

Semiannual Alumni Day.—The University of California Medical School, San Francisco, will hold its semiannual alumni day, March 22. The morning session will be devoted to operative clinics, pediatric ward rounds and a medical staff conference. In the afternoon the program will include addresses by Drs. Albert H. Rowe, Oakland, on allergic migraine and indigestion; Albert P. Krueger, indications and limitations of bacteriophage therapy; John B. Saunders, developmental pathology of congenital dislocation of the hip joint; Theodore L. Althausen, intolerance to carbohydrate associated with pathological intestinal flora; James F. Rinehart, monocytic leukemia; Dudley W. Bennett, treatment of certain types of heart disease, and the annual Alpha Omega Alpha lecture by Dr. John C. Meakins, Montreal, Que.

COLORADO

Two Years Without Diphtheria.—No diphtheria has been reported in Pueblo since Jan. 17, 1930, it is stated. This record was attained as the result of an extensive immunization campaign among school children and the control of persons described as diphtheria carriers who were discovered after cultures were taken by the health department.

Society News.—Dr. James R. Jaeger, Denver, addressed the Boulder County Medical Society, February 11, on "Diagnosis of Brain Lesions by Air Injection." Motion pictures on "The Repair of the Perineum" and "The Anatomy of the Female Pelvis" were shown before the Medical Society of the City and County of Denver, February 16.

Annual Registration Due March 1.—All practitioners of medicine and surgery holding licenses to practice in Colorado are required by law to register annually on or before March 1, with the secretary-treasurer of the board of medical examiners, and to pay a fee of $2, if a resident of Colorado, or $10, if a nonresident. Failure to pay this fee within the time stated automatically suspends the right of a licentiate to practice while delinquent. If he nevertheless continues to practice he is subject to the penalties provided by law for practicing medicine without a license.

FLORIDA

Adopt Plan for Cancer Clinic.—The Hillsborough County Medical Society, at a recent meeting in Tampa, approved a plan of operating a cancer clinic under the auspices of the society. Following the adoption of the plan, a committee was appointed to investigate the best methods of procedure to carry out the project. This committee comprises Drs. Bundy Allen, chairman; Robert P. Henderson, Jr., secretary; Emory W. Bitzer; William P. Adamson, and John R. Boling. Before the plan was submitted to the county medical society, a temporary organization was formed by a group of physicians in Tampa. Although the clinic will be principally for the study of cancer, it will be ready to support other types of medical research. Funds for its support have been offered by outside sources, it is reported. The money the clinic expects to receive will not be used for fees or salaries but to pay for material to be used in treatment of patients without cost to them.

ILLINOIS

Health Promotion Week.—Dr. Andy Hall, state director of public health, announces that health promotion week will be observed in Illinois, April 24-30. The announcement states that prevailing health conditions, which were never more favorable, are a tribute to the foundations on which scientific preventive medicine and public health service are built.

Health in 1931.—Provisional statistics indicate that mortality from tuberculosis and diphtheria, which, respectively, caused rates of 61.2 and 4.8 per hundred thousand, dropped to new low levels in Illinois during 1931. The general death rate was 11.1 per thousand people, a slight increase over the 10.9 rate of 1930 but lower than any previous record except that of 1921, which was identical. The average annual death rate of 11 for the two years of 1931 and 1930 was the lowest for any two successive years since Illinois was admitted to the U. S. death registration area. Typhoid caused 125 deaths during 1931, giving a rate of 1.6 against a previous low of 1.4 for 1929. The rates from pneumonia (71.6), influenza (21.3) and measles (4.3) were principally responsible for the rise in the general death rate. Poliomyelitis caused 101 deaths, a rate of 1.3, which was almost identical with the 1927 report.

Chicago

Institute for Tuberculosis Workers.—A two weeks' institute for tuberculosis workers, primarily laymen, will be conducted at Northwestern University Medical School, April 4-16. It will be conducted by the National Tuberculosis Association in cooperation with the medical school and the Chicago Tuberculosis Institute, and will be under the direction of Philip P. Jacobs, Ph.D., director of the extension service of the association. The registration fee is $10. Application blanks may be obtained from the state tuberculosis secretaries, or from the National Tuberculosis Association, 450 Seventh Avenue, New York. Topics for discussion will include child health education, case findings, care of physically substandard children, public health nursing, industrial health service, treatment methods, relation of the tuberculosis campaign to other social and public health movements, relation of the tuberculosis movement to the medical profession, and medical and scientific basis of the tuberculosis campaign.

IOWA

Society News.—Dr. Roy W. Tandy, Morning Sun, addressed the Louisa County Medical Society in Morning Sun, Dec. 10, 1931, on "Intravenous Therapy."——The Sioux County Medical Society was addressed in Hawarden, Dec. 10, 1931, by Dr. Archibald F. O'Donoghue, Sioux City, on "Compression Fractures of the Spine and Their Treatment by the Jack Method" and "The Rise of Skeletal Traction Apparatus in Treatment of Fractures, Especially Comminuted Fractures."——Dr. Jay F. Auner, Des Moines, conducted a clinic on skin diseases before the Washington County Medical Society, Dec. 1, 1931.——Dr. Emerson B. Dawson, Fort Dodge, addressed the Webster County Medical Society's annual meeting, Dec. 15, 1931, on sterility.——Dr. Wayne J. Foster, Cedar Rapids, read a paper on brain abscesses originating with ear infections before the all-day meeting of the Iowa Academy of Ophthalmology and Otolaryngology, Dec. 1, 1931, and Dr. Frederick L. Wahrer, Marshalltown, discussed the electrocoagulation of tonsils.——The Upper Des Moines Medical Society was addressed, Dec. 10, 1931, by Drs. Donald F. Rodawig, Spirit Lake, on "Craniocerebral Injuries"; Leslie G. Hill, Estherville, "Diagnosis and Treatment of Iritis"; Charles C. Collester, Spencer, "Diagnosis of Encephalitis and Conditions with Allied Symptoms," and Paul O. Nelson, Ayrshire, "Treatment of Pernicious Anemia."——At the meeting of the Waterloo Medical Society, Dec. 15, 1931, Drs. Charles Anderson Aldrich, Winnetka, Ill., and Harrold A. Bachmann, Chicago, spoke on "Nephritis in Children" and "Heart Findings in Children," respectively.——At the meeting of the Des Moines Academy of Medicine and the Polk County Medical Society, January 26, the speakers were Drs. Carl L. Gillies, Cedar Rapids, on "Charcot Joint"; Benjamin F. Wolverton, Cedar Rapids, "Subacute Bacterial Endocarditis," and Jesse T. Grayston, Marion, "Acute Mechanical Intestinal Obstruction."——The Marshall County Medical Society was addressed in Marshalltown, January 5, by Drs. Walter D. Abbott and Harry A. Collins, Des Moines, on "Injection of the Sympathetic Nervous System" and "Narcolepsy," respectively.——Dr. Robert L. Parker and Mr. Vernon Blank addressed the Jasper County Medical Society in Newton, January 5, on "County Contract for Care of the Indigent Sick."——The Linn County Medical Society will be addressed, March 10, by Dr. William R. Cubbins, Chicago, on "Injuries to the Menisci and Cruciate Ligaments of the Knee Joint." Dr. Howard L. Van Winkle, Cedar Rapids, will also speak on "Blood Transfusion." The society was addressed, February 11, by Drs. Fred M. Smith, Iowa City, and Arthur W. Erskine, Cedar Rapids, on "Rheumatic Heart Disease" and "Graham-Cole Test," respectively.

LOUISIANA

Dr. Castellani Returns to New Orleans.—Dr. Aldo Castellani, London, England, has accepted the position of professor of tropical medicine and head of the department at the Louisiana State University Medical Center, New Orleans. His appointment is for the year 1932-1933. Dr. Castellani resigned from a similar position at Tulane University of Louisiana School of Medicine in 1929 to devote full time to work in connection with a study of tropical diseases at the Ross Institute of Tropical Medicine, London, of which he was director. Dr. Castellani was born in Florence, Italy, but spent most of his childhood in England.

Personal.—Dr. Henry O. Colomb, formerly of Providence, R. I., has been appointed clinical director of Central Louisiana State Hospital, Pineville.——An honorary fellowship of Ross Institute for Tropical Diseases, London, has been conferred on Dr. Charles C. Bass, dean and professor of experimental medicine, Tulane University of Louisiana School of Medicine, New Orleans, "in recognition of his important discoveries with regard to malaria," with especial reference to his accomplishment of the first successful cultivation of the malaria parasite outside the human body. The Ross Institute was founded in honor of Sir Ronald Ross, the discoverer of the mode of transmission of malaria by mosquitoes.

Society News.—The Orleans Parish Medical Society was addressed, recently, by Dr. Charles A. Bahn on "Headaches of Ocular Origin," and by Dr. Oscar W. Bethea, "Some Deductions from the Analysis of 1,850 Physical Examinations." At another recent meeting of the society, the speakers were Drs. Alfred C. King on "Some Critical Remarks on the Whys and Wherefores of Bad Results in Certain Fractures"; Reginald A. Cutting, "The Place of Dextrose Phleboclysis in Surgery," and Thomas B. Ayo, "Induction of Labor with Castor Oil, Quinine and Puncture of the Membrane." Dr. Adolph Jacobs addressed the society's meeting, January 25, on "Sedimentation Rate of Erythrocytes; Brief History and Discussion of Theories; Application in Gynecology," and Dr. Howard R. Mahorner spoke on "Goiter: A Brief History of Its Surgery and a Review of 128 Operated Cases in a Non-Goiter District."

Health Control in Flooded Areas.—Floods along the Red and Ouachita rivers and the lower Tensas Basin have driven from their homes about 20,000 people in ten parishes, according to a report, February 12. The flood of 1927 demonstrated the value of organized parish full time health units and since that time a unit has been established in every parish in the flooded area except one. The present emergency is being met by the state board of health through these units, which may be mobilized in part or in their entirety for service in any parish or section where the necessity may arise. Refugee camps have been located at strategic points; sanitary measures have been instituted, and immunization of the refugees against smallpox, typhoid and diphtheria has been carried out by the local health units under the direction of the state board of health. Constant supervision is being exercised in order to prevent an outbreak of any communicable disease. Up until the time of this report, no epidemics had occurred.

MARYLAND

Commemoration Exercises at Johns Hopkins.—At the exercises commemorating the fifty-sixth anniversary of the Johns Hopkins University, February 22, portraits of four past and present faculty members will be presented to the university. Joseph S. Ames, LL.D., president of the university, will preside, and Sir Wilmott Lewis, Washington correspondent of the London *Times*, will be the principal speaker. George F. Baker, Jr., New York, will present a portrait of Dr. William H. Wilmer, professor of ophthalmology in the school of medicine and head of the Wilmer Ophthalmological Institute, Johns Hopkins Hospital, since 1925. The painting is the work of Frank O. Salisbury, London. Dr. William H. Welch, professor emeritus of the history of medicine, will present a portrait of the late Dr. William S. Halsted, first professor of surgery in the school of medicine. Dr. William S. Thayer, professor emeritus of medicine, will present a portrait of Dr. Frederick H. Baetjer, professor of clinical roentgenology. Both of these portraits are the work of Eric Haupt. William Seifriz, Ph.D., professor of botany, University of Pennsylvania, will present a portrait of Duncan Starr Johnson, Ph.D., professor of botany and director of the Botanical Laboratory and the Botanical Garden, Homewood, Johns Hopkins University. Thomas C. Corner, Baltimore, painted the portrait.

Society News.—Dr. John Ruhräh, Baltimore, addressed the Osler Society of the Medical and Chirurgical Faculty, January 19, on "Art and Pediatrics."——The Baltimore City Medical Society was addressed, January 8, by Drs. Lloyd W. Ketron on "Tuberculosis of the Skin," and George W. Crile, Cleveland, "Principles Involved in and Clinical Aspects of Denervation of the Adrenal Glands." The society was addressed, January 22, by Drs. Llewellyn Williams Lord on "The Etiology of Pityriasis Rosea"; Leo Brady, "Carbuncle of the Kidney," and Francis J. Kirby, "Cancer of the Breast."——The Baltimore County Medical Association was addressed, January 20, at Catonsville by Drs. Robert E. Garrett on "A Case of Addison's Disease with a Depressive Psychosis," and Silas W. Weltner, "A Behavior Study of a Group of Constitutional Psychopathic Inferiority Cases."——Dr. Francis Dana Coman addressed the Maryland Academy of Sciences recently on the Byrd South Pole expedition.——Dr. Claude S. Beck, Cleveland, addressed the Johns Hopkins Medical Society, Baltimore, February 8, on "Surgical Treatment of Pick's Disease and Pneumocardiac Tamponade in Relation to Surgery of the Heart."——A free maternity clinic for outpatients was dedicated at Sinai Hospital, Baltimore, January 17. The clinic is a gift of the Baltimore Chapter number 35, United Order of True Sisters, which has equipped and will maintain it. Dr. Alan F. Guttmacher will be in charge.

MASSACHUSETTS

Bill Introduced.—H. 1084, to amend the nursing practice act, proposes that all applicants for registration as nurses be citizens of the United States.

Health at Lowell.—Telegraphic reports to the U. S. Department of Commerce from eighty-three cities with a total population of 36 million, for the week ended February 6, indicate that the highest mortality rate (20.9) appears for Lowell, and the rate for the group of cities as a whole, 11.8. The mortality rate for Lowell for the corresponding period last year was 15.1, and for the group of cities, 14.3. The annual rate for eighty-three cities for the five weeks of 1932 was 12, as against a rate of 14.4 for the corresponding period of the previous year. Caution should be used in the interpretation of these weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits, or that they have large Negro populations, may tend to increase the death rate.

Mental Hygiene Courses.—The Massachusetts Society for Mental Hygiene and the state division of university extension are [illegible] ucting courses on mental hygiene. Dr. [illegible] Topeka, Kan., opened the course, February 1, in Boston, speaking on "The Human Mind—Personal Applications of Mental Hygiene," and Dr. Wilhelm E. Blatz, Toronto, spoke, February 8, on "The Young Child's Needs." In the future, the program includes Dr. Douglas A. Thom, Boston, February 15, on "Normal Youth and Its Everyday Problems"; Dr. Samuel W. Hartwell, Worcester, February 29, "How Bad Are 'Bad' Boys?"; Dr. Bruce B. Robinson, Newark, N. J., March 7, "Mental Hygiene in the Schools"; Dr. Edgar Van Norman Emery, New Haven, March 14, "Importance of the Teacher's Mental Health"; Dr. George H. Preston, Baltimore, March 21, "Parental Attitudes Reflected in the Home," and Dr. Albert Warren Stearns, Boston, March 28, "Crime in the Present Day." In Framingham, a course began, January 27, on "Mental Hygiene of Childhood and Adolescence"; in Melrose, January 20, "Personal and Social Aspects of Mental Hygiene," and in Orange, January 26, on "Mental Hygiene of Childhood and Adolescence."

MICHIGAN

Society News.—Dr. James Milton Robb, Detroit, addressed the Monroe County Medical Society, January 21, on "The Economics of Medicine."——A symposium on functions and disorders of the kidneys was included in the program of the annual meeting of the Washtenaw County Medical Society.——Dr. E. Starr Judd, Rochester, Minn., addressed the Wayne County Medical Society, February 16, on "Relation of the Physician to the Community." A dinner was given in honor of Dr. Judd preceding the meeting.——Dr. Robert E. Cumming, Detroit, addressed the Kalamazoo Academy of Medicine, February 16, on "Kidney Infections."

Typhoid Outbreak Follows Wedding.—Two fatalities resulted from an outbreak of typhoid, which followed a recent Polish wedding in Bay City. More than twenty persons were ill following the wedding. It was found that one small group of persons who had handled a portion of the food had had typhoid seven years previously. Tests on all but one of the group gave negative results. This person proved to be a carrier. According to Dr. George W. Moore, the health officer, the points of interest in this outbreak are, first, the seven year interval between the attack of typhoid and its transmission at the wedding; second, the fact that so far as known no other transmission has taken place during these seven years.

Dental Care for Semi-Indigent Children.—Plans to provide dental attention for semi-indigent children, at reduced fees and to reopen the health department's free clinics by means of volunteer service were formulated, January 16, at a meeting of the relief committee of the Detroit District Dental Society, it is reported. A city-wide examination of school children began, January 25, through the cooperation of dental inspectors from the health department and members of the society. The plan is to aid children whose parents ordinarily have the means to pay the full cost but are now in straitened circumstances and refuse charity. It is expected that volunteers from the society's membership will staff the thirty-two clinics of the health department.

Camp for Handicapped Children.—The W. K. Kellogg Foundation has provided for the establishment of a permanent fresh air camp for physically handicapped children, involving an expenditure of about $100,000. The plans of the W. K. Kellogg Foundation Pine Lake Camp, as it will be known, call for the erection of an administration building, staff quarters, small emergency hospital building and twenty-four unit cottages, and will provide accommodations for 200 handicapped children for an eight or nine weeks' camping period every summer; July 1 is the date designated for its opening. The site chosen on Pine Lake is desirable, it is reported, because of the ideal shoreline, particularly suitable for sunlight and air bath treatments for handicapped children. The staff of the camp will include physical therapists, chief and regular counselors, secretary, quartermaster and dietitian. Dr. Matthew R. Kinde, medical director of the Barry County health unit, will act as medical director of the camp.

MISSOURI

Urological Society Formed.—The St. Louis Urological Society, organized January 7, proposes to aid scientific urology in St. Louis, to cooperate with the St. Louis Medical Society and to promote fellowship among its members. Dr. Bransford Lewis was elected president; Dr. Joseph Hoy Sanford, vice president, and Dr. Grayson L. Carroll, secretary. Drs. John R. Caulk, Cyrus E. Burford and Helmuth H. Kramolowsky were named members of a committee to formulate a constitution and by-laws to be presented at a called meeting in the spring, according to the *Journal of the Missouri Medical Association.*

Society News.—A discussion of arthritis by Dr. Wilber E. Post, Chicago, was a feature of the monthly clinic of the Kansas City Southwest Clinical Society, February 9. In the evening, the Jackson County Medical Society was addressed by Dr. Post on "Recent Advances in Nephritis"; Dr. Ferdinand C. Helwig conducted a pathologic conference, and Dr. Frederick C. Narr presented "Microscopic and Macroscopic Demonstrations of Pathology of the Kidney."——Dr. Walter C. Alvarez, Rochester, Minn., addressed the Kansas City Academy of Medicine, February 19, on "Practical Application of Recent Discoveries in the Field of Gastro-Intestinal Physiology."——Dr. George W. Robinson, Jr., among others, addressed the Jackson County Medical Society, Kansas City, February 16, on "Cause and Treatment of Paraplegia."

NEW JERSEY

Bill Introduced.—A. 164, to amend the law regulating the practice of chiropractic, proposes that licensed chiropractors be "authorized to use in connection with hand manipulation and adjustment such adjuncts, substitutes or other means or methods in conjunction with chiropractic treatment without the use of drugs as may be essential or necessary to conform to the modern methods of treatment."

Society News. — The Essex County Medical Society was addressed, February 12, by Dr. Livingston Farrand, Ithaca, N. Y., on "Report of the New York State Health Commission."——At the meeting of the Bergen County Medical Society, February 9, Drs. Joseph M. Kuder, Mount Holly, spoke on "Public Relations and the County Medical Society," and Frank L. Meleney, New York, "Recent Studies in Peritonitis."——An addition to the Underwood Hospital, Woodbury, will be built and equipped by Mrs. Ella D. Dunn and her family, as a memorial to her husband, John C. Dunn, for many years a manufacturer in Camden.

NEW YORK

Bills Introduced.—S. 533 and A. 598, to amend the pharmacy act, propose (1) that a drug be deemed misbranded, within the meaning of the act, if its container does not state the percentage contained therein of barbituric acid and (2) that the manufacture and sale of proprietary medicines be exempt from the operation of the act, provided such medicines contain no poisonous, deleterious or habit-forming drugs. S. 624 proposes to prohibit the sale of food in drug stores and pharmacies and to make it unlawful for any druggist or pharmacist to dispense any beverage on the same day that he dispenses drugs. S. 635 and A. 793, to amend the law regulating the practice of midwifery, propose to limit the registration of midwives to those applicants possessing a diploma from a school of midwifery recognized by the state commissioner of health. The commissioner, it is proposed, however, may renew the license of any midwife now licensed. S. 675 proposes to regulate the practice of barbering. A. 684, to amend the workmen's compensation act, proposes, in effect, to make compensable any occupational disease contracted in any employment covered by the act. A. 754, to amend the dental practice act, proposes that any woman who for four years prior to Sept. 1, 1916, was continuously in the employ of a licensed dentist and had acquired experience in oral hygiene, shall be licensed as a dental hygienist without examination.

New York City

First Nurse-Midwife Training School.—The first training school for graduate nurses in midwifery in the United States was opened, February 2, at the Lobenstine Midwifery Clinic, 274 West One Hundred and Thirteenth Street. This clinic will care for expectant mothers living in a restricted area. The work will be under the supervision of the following board of directors: Drs. George W. Kosmak, president, Benjamin P. Watson, George Gray Ward, Jr., George L. Brodhead, Shepard Krech, Linsly R. Williams and Miss Hazel Corbin. The attending staff includes Drs. William H. Studdiford, Jr., Donato Anthony d'Esopo, Claude Edwin Heaton and Albert H. Aldridge. The necessary budget was provided by Mrs. E. Marshall Field and a group of sixty women as a memorial to the late Dr. Ralph Waldo Lobenstine. This venture is a part of the plan for midwife training and supervision proposed by the Association for the Promotion and Standardization of Midwifery, which was recently incorporated in New York. One of the objects of this teaching clinic will be to supply health departments with well trained nurse-midwives to carry out such supervision under medical direction, and another will be to offer courses to midwives practicing in the city. It was pointed out that about 10 per cent of all the births in the city are attended by midwives.

Society News.—Dr. William H. Park addressed the Public Health Officers Association of the City of New York, February 2, on "Epidemiology and Serum Treatment of Poliomyelitis."——Drs. Linsly R. Williams and Edward H. Hume discussed graduate medical education at the monthly postgraduate lecture session of the North Harlem Medical Society, January 22.——Dr. Harold Neuhof addressed the Medical Society of the County of Queens, January 26, on "Recent Clinical Advances in the Pathogenesis, Diagnosis and Surgical Treatment of Lung Abscess."——At a meeting of the Queensboro Surgical Society, January 18, Dr. Howard W. Neail discussed abortions.——Dr. John J. Moorhead addressed the New York Surgical Society, January 27, on "Further Experiences with Knee Joint Arthrotomy."——Dr. George Draper delivered an address on "Relation of Human Constitution to Disease, with Particular Reference to Peptic Ulcer and Infantile Paralysis" before the New York Physicians' Association, January 27.——A symposium on malignant conditions of the colon was held at the stated meeting of the New York Academy of Medicine, February 4, with the following speakers: Drs. Howard T. Karsner, Cleveland; Thomas R. Brown, Baltimore; Byrl R. Kirklin and Fred W. Rankin, Rochester, Minn.——Dr. Charles Geschickter, Baltimore, addressed the New York Roentgen Society, February 15, on bone tumors.——Drs. Samuel Brock and Cornelius G. Dyke, among others, addressed the New York Neurological Society, February 2, on "Cerebral Blood Vessel Malformations."——The Central Medical Council, composed of the membership of five leading medical societies in Brooklyn, gave a dinner, January 27, in honor of Dr. William Linder, recently elected president of the Kings County Medical Society.——Dr. James E. King, Buffalo, will lecture at the New York Post-Graduate Medical School and Hospital, February 23, on "Backache in Women and the Value of the Pessary." Dr. King will also hold an operative clinic.

OKLAHOMA

Course in Obstetrics.—About 500 physicians from Oklahoma County and neighboring counties registered for the graduate lectures on obstetrics in Oklahoma City during the afternoon and evening of January 23. The guest speakers were Drs. Everett D. Plass, Iowa City, Iowa; William T. McConnell, Louisville, Ky., and James R. Manley, Duluth, Minn. These physicians gave a similar course in Osage, Carter, Greer and Caddo counties.

Society News.—Dr. Richard L. Sutton, Jr., Kansas City, Mo., addressed the Craig County Medical Society at Vinita, recently, on diagnosis and treatment of cancer of the skin; he also gave a travel lecture and held a dermatologic clinic.——Drs. Louie F. Barney, Kansas City, Kan., and Abraham L. Blesh, Oklahoma City, addressed the Ottawa County Medical Society, Dec. 18, 1931, at its annual banquet and game dinner at Miami, on "Treatment of Acute Generalizing Peritonitis" and "Medical and Surgical Reminiscences," respectively.——Physicians of western Oklahoma attended a special meeting sponsored by the University of Oklahoma School of Medicine, January 20, at Mangum. The speakers were Drs. Everett D. Plass, Iowa City, who discussed management of normal pregnancy, sterilization and contraceptive advice; James R. Manley, Duluth, Minn., vaginal discharge during pregnancy and puerperal sepsis, and William T. McConnell, Louisville, Ky., prenatal care and toxemias of pregnancy. ——At a recent meeting of the Southern Oklahoma Medical Association in Purcell, speakers included Drs. George E. Johnson, Ardmore, on "Physiological and Pathological Conditions of the Thyroid"; Walter H. Livermore, Chickasha, "Spinal Anesthesia"; George S. Barger, Purcell, "Tonsils from the Standpoint of the General Practitioner and Specialist," and Rufus Q. Goodwin, Oklahoma City, "Relation of the Physician to the Patient."——The medical societies of Woods and Alfalfa counties held a joint meeting at Holdenville, January 26, with three speakers from Oklahoma City on the program, as follows: Drs. Henry Turner, "Interrelationship of Endocrinology"; Horace Reed, "Differential Diagnosis of Abdominal Conditions," and Philip McNeill, "Nontuberculous Infections of the Lungs."

OREGON

Licenses Revoked.—The licenses of Drs. Wilbur H. Thompson, Elgin, Chester A. Bump, formerly of Portland and now of San Francisco, and Joseph A. Wonderlick, La Grande, have recently been revoked by the Board of Medical Examiners of the State of Oregon for unprofessional conduct.

Society News.—Dr. Franklin G. Ebaugh, Denver, addressed the Portland City and County Medical Society, January 20, on psychiatry.——Dr. Loyal Davis, Chicago, addressed a joint meeting of the Portland City and County Medical Society and Portland Academy of Medicine, February 3, on studies on the pathways of transmission of pain, and its surgical relief.

PENNSYLVANIA

Personal.—Dr. Norman R. Goldsmith, Pittsburgh, won the annual case report contest of the Allegheny County Medical Society. The medical society has conducted this contest for interns for the past six years. Dr. Goldsmith is an intern at Mercy Hospital.

Society News.—Dr. Moses Behrend, Philadelphia, addressed the Northumberland County Medical Society, Shamokin, February 3, on the gallbladder. The society sponsored a public lecture at Sunbury, January 19, by Dr. William D. Stroud, on "The Presence of Heart Disease in Children."——At the meeting of the Lycoming County Medical Society, Williamsport, February 12, Drs. Albert F. Hardt, Williamsport, and Edward Weiss, Philadelphia, spoke on "Points in the Diagnosis and Treatment of Acute Abdominal Disease" and "Recent Advances in Our Conception of Kidney Diseases," respectively.——Case reports comprised the meeting of the Muncy Valley Medical Association, January 20; the speakers were Drs. Harold F. Baker, Muncy, and Amos V. Persing, Jr., Allenwood.—— "Medical Science and Medical Art" was the subject of Dr. Edward J. G. Beardsley, Philadelphia, before the Cambria County Medical Society, February 11; "Research and Study: A Review" was discussed by Drs. Leo W. Hornick, Kent A. Bowman and Calvin C. Rush, Johnstown.——At the meeting of the Delaware County Medical Society, February 11, Drs. John S. Eynon and Abraham Maxwell Sharpe, Chester, spoke on "Diagnosis and Treatment of Bone Tumors" and "X-Ray Aspect of Bone Tumors," respectively. Among others, J. DeHaven Ledward, Esq., Chester, addressed the annual meeting of the society, January 14, on "Expert Testimony."

Philadelphia

Society News.—The Philadelphia County Medical Society will hold a medical-dental night, February 24; the speakers will be Dr. Alfred Hess, New York, on "Nutritional Factors in Relation to Dental Caries"; Dr. Collin Foulkrod, "Nutrition of the Pregnant Woman in Its Relation to Dental Health and Disease of Mother and Child," and Percy R. Howe, D.D.S., Boston, "Nutritional Aspects of Dental Disturbances." Dr. Temple S. Fay delivered the weekly graduate seminar of the society, February 19, on "Intracranial Pressure Problems as Related to the General Practitioner."

Personal.—Dr. David H. Bergey, formerly professor of hygiene and bacteriology, University of Pennsylvania School of Medicine, has been appointed director of research in biology at the National Drug Company.——Dr. Catharine MacFarlane, head of the department of gynecology, Woman's Medical College of Pennsylvania, was recently elected a fellow of the Philadelphia College of Physicians. Dr. MacFarlane is said to be the first woman so honored in the history of the college, which was organized in 1787.——Joseph W. E. Harrisson, Pharm.D., has been appointed lecturer in physiologic assaying at the Philadelphia College of Pharmacy and Science.

Changes in Health Department.—Dr. Seth A. Brumm has been appointed chief of the division of communicable diseases of the Philadelphia Department of Public Health. The division of tuberculosis, as such, has been abolished, and its administration transferred to the division of communicable diseases. The change in administration discontinues Dr. Charles J. Haines, former chief of the division of communicable diseases, and Dr. Abraham J. Cohen, former chief of the division of tuberculosis. Three hundred and seventy-six employees were dropped from the department of public health, February 1. This revamping was necessary to operate the department effectively and economically, it was said.

Memorial to Dr. Sailer.—A marble memorial tablet and an endowment for a bed were presented to the Children's Heart Hospital, February 4, in honor of Dr. Joseph Sailer, founder of the hospital. The memorial was the gift of friends of Dr. Sailer from all over the country. Dr. Truman G. Schnabel made the presentation, and a eulogy of Dr. Sailer and his work was given by Dr. Wilmer Krusen. The hospital has a present capacity of 50 beds, but plans are being laid for the erection of additional wings and the ultimate enlargement of facilities to 200 beds. Dr. Sailer, who died in 1928, was professor of clinical medicine at the University of Pennsylvania School of Medicine. He was chairman of the Section on Gastro-Enterology and Proctology of the American Medical Association, 1927-1928.

TENNESSEE

University News.—The Rockefeller Foundation recently granted $250,000 to Vanderbilt University School of Medicine for a research fund, with the understanding that a supplementary amount shall be secured by the authorities of the school. An appropriation of $50,000 was made by the General Education Board for the medical library. The research fund will be divided and distributed over a period of eight years, while the medical library grant will be distributed over a period of four years. Dr. Thomas S. Cullen, professor of clinical gynecology, Johns Hopkins University School of Medicine, delivered the Phi Beta Pi lecture at Vanderbilt University School of Medicine, February 16, on "Gynecology of Yesterday and of Today."

Society News.—About 300 health workers attended the annual conference of health workers in Nashville, January 18-20, under the chairmanship of Dr. Eugene L. Bishop. Among speakers were Dr. John A. Ferrell and Louis I. Dublin, Ph.D., both of New York; Dr. Clifford E. Waller and Dr. Walter T. Harrison of the U. S. Public Health Service, and J. A. Le Prince, sanitary engineer of the public health service. Subjects discussed included control of tuberculosis, diphtheria, venereal disease and malaria, sanitation, city and county health work, vital statistics, maternal and infant mortality and typhoid in rural and urban areas.——Dr. William D. Hickerson, Nashville, addressed the Williamson County Medical Association in January on tuberculosis in Tennessee. ——Dr. Manton L. Shelby, among others, addressed the Montgomery County Medical Society, Clarksville, January 20, on myelogenous leukemia.——Dr. Carl R. Crutchfield addressed the Nashville Academy of Medicine, February 5, on "Spinal Anesthesia," with report of more than 250 cases.

VERMONT

Personal.—Dr. Charles Gordon Abell, Enosburg Falls, has been appointed a member of the state board of health to succeed Dr. Edward J. Rogers, Pittsford, who resigned recently. Dr. Rogers had been a member of the board for nine years and chairman for several years.——Dr. Merritt H. Eddy, Middlebury, celebrated his ninety-ninth birthday, January 25; he is said to be the oldest licensed, practicing physician in New England. On his ninety-eighth birthday Dr. Eddy laid the cornerstone for the New England Medical Center in Boston (The Journal, March 28, 1931, p. 1091).

GENERAL

Examination in Otolaryngology.—The American Board of Otolaryngology will hold an examination, September 17, at the Royal Victoria Hospital, Montreal. Application blanks may be procured from the secretary, Dr. William P. Wherry, 1500 Medical Arts Building, Omaha, Neb. The meeting of the American Academy of Ophthalmology and Otolaryngology will be held in Montreal, September 19-23, with headquarters in the Mount Royal Hotel.

Four Weeks of Automobile Fatalities.—The U. S. Department of Commerce announces that, during the four weeks ended January 23, eighty-three large cities in the United States reported 867 deaths from automobile accidents, as compared with 742 deaths during the four weeks ended Jan. 24, 1931. Most of these deaths were the result of accidents that occurred within the corporate limits of the city, although some accidents occurred outside the city limits. For the fifty-two week periods ended Jan. 23, 1932, and Jan. 24, 1931, the totals for all the cities were, respectively, 9,140 and 8,927, which indicates a recent rate of 25.6 per hundred thousand of population.

Celebration of Discovery of Tubercle Bacillus.—In celebration of the fiftieth anniversary of Robert Koch's announcement of his discovery of the tubercle bacillus, a special translation of Koch's original paper of March 24, 1882 (*Berl. klin. Wchnschr.* **19**:221-230, 1882), published for the first time in English, is being printed by the National Tuberculosis Association. A copy will be given free to each senior student in every grade A medical college in the United States. It is planned to have another edition of the booklet for sale and distribution through state tuberculosis and health associations. The association is also planning to observe the anniversary nationally through newspapers, news reels and broadcasting, and will provide special material and suggestions to assist local societies in working up a program. The bulletin of the association points out that Koch's anniversary precedes the beginning of the annual early diagnosis campaign by seven days.

Pacific Coast Surgical Association.—The seventh annual meeting of the Pacific Coast Surgical Association will be held at the Biltmore Hotel, Santa Barbara, Calif., February 25-27, under the presidency of Dr. Rea E. Smith, Los Angeles. Speakers will include Drs. Park Weed Willis, Seattle, on "Appendicitis—When to and When Not to Operate"; Richard B. Dillehunt, Portland, "Reconstruction of Disabled Elbows in Children"; Samuel L. Caldbick, Everett, Wash., "Endothelioma of the Stomach"; Horace G. Wetherill, Monterey, Calif., "Surgical Aspects of the Treatment of Mental Defectives, Sexual Perverts and Criminals"; Albert J. Scholl, Jr., Los Angeles, "The Ureter After Nephrectomy," and Karl F. Meyer, Ph.D., San Francisco, "Newer Knowledge of Tetanus." Prof. Shiota Matsuoka of the University of Tokyo, Japan, will address a meeting, Wednesday evening, on "A Comparison of Surgical Methods Used in Japan and America." An extensive program of entertainment has been arranged.

Phillips Memorial Prize Awarded to Dr. Avery.—The American College of Physicians has selected Dr. Oswald T. Avery of the Rockefeller Institute for Medical Research, New York, as the recipient of the first John Phillips Memorial Prize. This award of the sum of $1,500 was established by the college to perpetuate the memory of Dr. John Phillips, Cleveland, who lost his life in the Cleveland Clinic disaster, May 15, 1929. The presentation will be made to Dr. Avery during the annual clinical session of the college in San Francisco, April 6, when he will deliver an address on "The Rôle of Specific Carbohydrates in Pneumococcus Infection and Immunity." The recommendation of the committee which made the selection cites Dr. Avery's work on the pneumococcus, "beginning with the discovery of the type-specific soluble capsular polysaccharides and culminating in the discovery of a bacterium producing an enzyme which splits the polysaccharides of type 3 pneumococcus in vitro, thus rendering it susceptible to phagocytosis and thereby protecting the animals infected with it."

Medical Bills in Congress.—*Change of Status:* S. 100 has been favorably reported to the Senate, amending the laws of the District of Columbia relating to degree-conferring institutions so as to authorize any institution heretofore incorporated under such laws, operating exclusively in a foreign country, to use the words "American," "Federal," etc., in its title (Senate Report No. 236). H. R. 4724 has been favorably reported to the House, without amendment, conferring the benefits of hospitalization and the privileges of soldiers' homes on certain persons who served in the Quartermaster's Corps or under the jurisdiction of the Quartermaster General during the war with Spain, the Philippine insurrection or the China relief expedition (House Report No. 432). *Bills Introduced:* S. 3226, by Senator Sheppard, Texas, to extend the benefits of the Emergency Officers' Retirement Act to provisional officers of the Regular Establishment who served during the World War. S. 3530, by Senator Blaine, Wisconsin, to amend the Longshoremen's and Harbor Workers' Compensation Act so as to deny compensation to an employee who unreasonably refuses to submit to medical or surgical treatment. S. 3591, by Senator McGill, Kansas, to amend the World War Veterans' Act to provide, among other things, that in considering claims the same credence shall be given to the statements of physicians in private practice as is given to the statements of physicians attached to the Veterans' Administration, "and the statements of lay physicians shall be presumed to be true until proven false." H. R. 8979, by Representative Johnson, Oklahoma, and H. R. 8993, by Representative Cartwright, Oklahoma, to liberalize the disability allowances for veterans of the World War suffering from disabilities contracted in civil life. H. R. 9139, by Representative Kahn, California, to erect a veterans' hospital in California to be used exclusively for women veterans.

FOREIGN

Sir Norman Walker Elected President of British Council.—Sir Norman Walker, Edinburgh, was elected president of the General Medical Council of Great Britain at its meeting in London, recently, succeeding Sir Donald MacAlister, whose health has been impaired by a long illness. Sir Norman has served as direct representative on the council for Scotland since 1907. He was president of the Royal College of Physicians of Edinburgh from 1929 until Dec. 3, 1931, when Dr. Robert Thin was elected to succeed him. In connection with his work for the council he has visited India, Canada and the United States. In 1928 he was the guest of the Council on Medical Education and Hospitals of the American Medical Association at the annual congress. Sir Donald MacAlister had been president of the council since 1904 but had been a member since 1889, a total service of forty-two years.

Medical Relief in China's Flood District.—The department of hygiene and sanitation of the National Flood Relief Commission has devoted its efforts in the recent Yangtze River disaster to three main features: prevention of epidemics, public sanitation and medical relief. With a personnel of 72 physicians, 11 pharmacists, 65 nurses, 4 sanitary engineers, 72 sanitary inspectors, 25 secretaries and others, the department is maintaining six centers, of which the largest is in the Wu-Han area. Dysentery, malaria and typhoid appeared in epidemic proportions, according to the *National Medical Journal of China.* Thousands of inoculations for cholera and typhoid have been given; although cholera appeared in September, it abated with the coming of cooler weather. The winter was expected to bring louse-borne diseases such as typhus and relapsing fever in greater number, however. In view of the enormity of the task confronting the department, medical schools were requested to close temporarily in order to release both staff and students to participate in an antiepidemic campaign on a national scale.

Foreign Schools Restrict American Applicants.—A warning to American students, who are said to be flocking in great numbers to foreign medical schools, was contained in the January issue of the bulletin of the Institute of International Education. It is said that nearly 1,000 Americans were studying in schools of Europe and Canada alone last year. A study of the situation has shown that the majority of these students are those who have been refused admittance to American medical colleges. It appears that although the United States has the largest relative supply of physicians of any country in the world and that there is no apparent need for more, these facts are not a deterrent to the numbers of young persons who wish to study medicine. Within the past two years European schools have taken drastic measures to reduce the number of applicants. According to the bulletin, more than 200 were rejected at Edinburgh and the same number at Aberdeen, while Glasgow has had an American quota for two years. The hope is expressed that in the interest of the students themselves and of international good will, vocational advisers in colleges will present these facts with frankness to aspirants for the medical profession.

Society News.—The second General Congress on Child Welfare will be held in Geneva, Switzerland, July 18-21. The work of the congress will be divided into three sections as follows: section I, comparative study of experience in connection with children placed in foster homes and institutions; section II, the preschool child and section III, the post-school child. Further information may be obtained from the secretariat of the congress, care of the Save the Children International Union, 31 Quai du Mont-Blanc, Geneva.——An international congress on biliary lithiasis will be held at Vichy, France, September 19-22, under the chairmanship of Professor Carnot of the French Academy of Medicine. The congress will be divided into four sections: medicine, surgery, therapeutics and hydrology, and electroradiology and physical therapy. Papers are limited to five pages of forty lines each and must occupy only ten minutes' reading time. Full information may be obtained from the General Secretariat of the congress, 24 Rue des Capucines, Paris.——Sir Hubert Bond delivered the twelfth Maudsley Lecture of the Royal Medico-Psychological Association of England, Nov. 24, 1931, on the life and work of Maudsley.——The second assembly of the International Association of Prophylactic Pediatrics will be held in July at Geneva, Switzerland, under the chairmanship of Dr. Taillens. Topics to be discussed include infant mortality during the first week of life, prophylaxis of tuberculosis in schools, prophylaxis of syphilis in infants, control and regulations on milk to be given to infants, and respiratory diseases in young children.——The first national congress of the Italian Society of Oral Surgery and Dentofacial Orthopedics will be held at the University of Parma in May. This society was organized in November, 1931, in Parma, with Dr. Paolucci as honorary president.——The third International Congress on Sanitary Technic and Urban Hygiene, which will be held in Lyons, France, March 7-10, will be organized in six sections, as follows: transport hygiene, hygiene of habitations and places of assembly, hospitals and social work, atmospheric problems, disinfection and industrial hygiene, and prevention of accidents. There will also be an exhibit on these subjects. Information will be sent on application to Professeur Garin, commissionaire général, rue Ménestrier, Lyons.——The *Indian Medical World*, published in Calcutta, has changed its name to the *Journal of the Indian Medical Association*. The new name was first used with the issue of September, 1931.

Government Services

Surgeon General Cumming Reappointed

President Hoover has reappointed Dr. Hugh S. Cumming for another term of four years as surgeon general of the U. S. Public Health Service. The nomination was confirmed by the Senate, January 28. General Cumming was originally appointed to this position in February, 1920. He was born in Virginia, Aug. 17, 1869, and entered the public health service as assistant surgeon in 1894. On completion of his present reappointment, General Cumming will have served continuously in this office for sixteen years.

Army Personals

Lieut. Orlo C. Paciulli, relieved at Fort Crook, Nebraska, and assigned to duty in the Panama Canal Department, effective about March 10; Major James G. Hall, Fort Brown, Texas, for the convenience of the government, proceeded to his home about November 17 to await retirement; Major Frederick H. Sparrenberger and Capt. Harvey I. Rice, having been found incapacitated for active service on account of disability incident thereto, their retirement is announced; Major Myron P. Rudolph, on completion of present tour of foreign service, is assigned to duty in the Philippine Department; Capt. James O. Gillespie, on completion of present tour of foreign service, is assigned to duty at Fort Sam Houston, Texas; Col. Howard H. Baily, for the convenience of the government, proceeded to his home about Dec. 11, 1931, to await retirement; Capt. Lonzo R. Bice, having been found incapacitated for active service on account of disability incident thereto, and such finding having been approved by the President, his retirement is announced, effective Dec. 31, 1931. The following named officers, on completion of their present duties, will sail for the Philippine Department, about April 29: Majors Ralph E. Henry, Fort Thomas, Kentucky; John F. Lieberman, Washington, D. C.; Charles H. Lovewell, Fort Snelling, Minnesota; Robert Malcolm, Fort Moultrie, South Carolina; Irwin B. Smock, Fort Ethan Allen, Vermont, and Capts. Roary A. Murchison, Fort Benning, Georgia, and John R. Wood, Fort Hamilton, New York; Lieut. Col. Morrison C. Stayer, from Fort Benning, Ga., to Carlisle Barracks, Pa.; Major Dennis W. Sullivan, from Carlisle Barracks to Fort Sam Houston, Texas; Capt. Charles S. Sly, relieved from duty in the Hawaiian Department and assigned at Letterman General Hospital, San Francisco; Major Cyrus B. Wood, relieved at Army Medical School, Washington, D. C., and assigned to duty in the Hawaiian Department, about June 18; Major Sidney L. Chappell, on completion of tour of foreign service, and assigned to duty at the Army Medical Center; Major Patrick S. Madigan, relieved at Walter Reed General Hospital, Washington, D. C., and assigned to duty in Balboa Heights, C. Z.; Major Lucius F. Wright, relieved at Fort Williams, Maine, and assigned in the Hawaiian Department; Capt. Jack W. Schwartz, relieved at Fort Slocum, New York, and assigned in the Philippine Department; Major Charles M. O'Connor, Jr., relieved at the general dispensary, Washington, D. C., and assigned to Balboa Heights, C. Z.

Nutritional Anemia in Infancy

Before the war the form of anemia termed chlorosis was common among young women, especially those employed in shops and domestic service, but in consequence of better hygienic conditions this disease has disappeared. Through an investigation for the medical research council, Dr. Helen Mackay has shown that a not dissimilar anemia is prevalent among the infants of London, whether breast or bottle fed, and readily curable by administration of iron (with perhaps minute quantities of copper and manganese). The disease occurs in infants not obviously suffering from any other disease, acute or chronic, though it is frequently associated with bacterial infections and has therefore been termed simple anemia. Other terms that have been used by various writers are nutritional anemia, alimentary anemia of infective origin, cow's milk anemia, chlorotic anemia of infancy, oligosideremia and anemia of premature infants. All these show a similar blood picture, chlorotic in type; i. e., reduction of the hemoglobin percentage, often with little other change. Thus they constitute a single form of anemia. Bunge showed in 1902 that infants are dependent on the store of iron in the liver at birth, since the quantity in milk, human or cow's, is inadequate to provide the amount required for growth. Recent American experimental work goes to show that traces of copper and manganese are important in the cure of the "milk anemia" of young animals. The normal level of hemoglobin at birth appears to be not less than between 120 and 140 per cent; toward the end of the first month it sinks to not less than 99, in the second month to not less than 82, and in the third month to not less than 69. Thereafter the hemoglobin begins to rise, and from the sixth to the twelfth month it is not less than 80.

THE PREVALENCE OF ANEMIA IN INFANCY

Taking hemoglobin 10 per cent below normal as indicating anemia, 45 per cent of breast-fed infants under 12 months of age who were brought to clinics in the east end of London and 51 per cent of those artificially fed were anemic. At the beginning of the second year the figures were 42 and 70 per cent. Much of the anemia was of mild grade and might be considered unimportant had it not been shown to be responsible for much ill health. Nearly every premature infant and most twins acquired anemia, if untreated. In Vienna a worse grade of anemia was found than in London and the disease has also been observed in Berlin and New York. The anemia is equally common in summer and in winter.

ETIOLOGY

Why iron deficiency should occur in full-term infants on breast milk is still a riddle. It may be due to deficient store in the liver or to wasteful utilization, or there may be some controlling factor, comparable with vitamin D in calcium and phosphorus metabolism. Maternal factors may influence the amount of iron stored in the liver. Milk anemia may be produced in the young of experimental animals if the diet of the mother is deficient in iron. But anemia develops in infants whose mothers have had a mixed diet, including meat and green vegetables. The smaller the infant at birth the greater the likelihood that it will develop anemia, for the more rapidly will be the rate of growth relative to the initial weight and the more quickly will the iron store in the liver be exhausted. For the same reason the premature infant is liable to develop anemia. Diseases due to a great variety of causes, from hemorrhage to sepsis, may lower the hemoglobin level and create a call on the iron store of the liver which cannot be met. Anemia is more frequent in infants fed on cow's milk than in the breast fed because the iron intake is smaller and the percentage of retention less. If a diet low in iron, for instance one largely of milk and cereal, is continued after infancy the anemia will increase. Neither sunshine sufficient to tan the skin nor artificial light therapy has any curative or prophylactic value.

SYMPTOMS AND COURSE

Nutritional anemia is insidious in onset, and advice is often sought only for an intercurrent infection. Pink cheeks from an outdoor life or even a flushed skin from being near a fire may completely mask a hemoglobin level of 50 per cent. On the other hand, a child living in a dark basement may look pale though its hemoglobin is 80 per cent. The color of the lips is the best clinical indication, but unless anemia is severe, it is seldom possible to be dogmatic without examination of the blood. Nutritional anemia generally begins in breast-fed infants between the ages of 4 and 7 months. If the infant is weaned and given a mixed diet when between 8 and 9 months of age, improvement begins at about 10 months. In artificially fed infants the onset is earlier. The most important feature of this anemia is susceptibility to infections—colds, otorrhea, bronchitis and enteritis—which tend to become chronic and increase the death rate. The palish, fat infant is liable to pneumonia and a bad subject.

TREATMENT

All artificially fed and many breast-fed infants should be treated prophylactically, especially if the birth weight is low, and the treatment should be continued until the age of 12 months. Iron and ammonium citrate is a good preparation, as it usually contains traces of copper and manganese. It can be given in a sweetened mixture (1½ grains to the drachm) or incorporated in the dried milk used for feeding. The mother is told to begin with a few drops thrice daily, increasing gradually to 1 and then to 1½ drachms or more. For an infant weighing under 10 pounds, 4½ grains of the salt daily is probably sufficient. The mixture can be added to the feed, but it is important to begin the iron treatment gradually; otherwise, colic, vomiting or diarrhea may be produced. The treatment will raise the hemoglobin level of most infants over 5 months of age to the neighborhood of 80 per cent and increase the resistance to disease. Treatment should be begun before the age of 2 months, in premature infants at 4 weeks, and in infants who have lost blood from hemorrhagic disease a few days after the bleeding has ceased. Naturally, caution is required and the treatment should be even more gradual than in ordinary cases. Curative treatment should follow the same lines as prophylaxis, but the doses may be pushed higher, especially in older infants. It is difficult to understand why so many writers say that iron is ineffectual. The explanation of failures may be too short a period of treatment (little effect may be produced for a month or longer), pyogenic infections or alimentary disturbances, or the use of iron salts of low solubility or of absolute chemical purity.

Lectures to Graduates on Sundays

A recent development of postgraduate teaching in London is a course of lectures on Sunday at Charing Cross Hospital. The idea evidently is that Sunday is a convenient day for many busy physicians who would have difficulty in attending on week days. The present course runs from January 17 to March 20. Two lectures are given each Sunday, at 10:45 and 11:45 a. m.

London's Great Nursing Home

The London Clinic and Nursing Home, which will soon be ready to receive patients, will supply a great want. Outside the voluntary hospitals there has been little provision for persons of moderate means requiring medical or surgical treatment of a specialized kind. The home has been planned to supply this want. It is the largest nursing home ever built in this country. It combines the resources of a modern hospital with that of a first class hotel. There are luxury suites for patients who can pay for them, but a large number of the rooms are intended for middle class persons at an inclusive cost of $24 weekly. The only possible extra is the use of the operating theater, and this point remains to be settled. Mr. Ernest Morris, the house governor, who made his reputation in a similar position at the London Hospital, has the desire to be able to present what he describes as "a one-line bill" to those who use the home. There will be accommodations under one roof for thirty-six consulting physicians and surgeons, who will each have his own consulting suite with an entrance in Harley Street, complete equipment for comprehensive examination; and rooms for 214 patients. The site of the area of building is 2 acres and there are ten floors. Vibration and noise are practically eliminated by a special padded foundation, and the corridors, whose total length is a mile, are laid with rubber. Novel features have been introduced for such matters as ventilation. To secure the maximum of fresh air when weather conditions are suitable, the sashes of the patients' windows can be lowered below the sill. Each room has running hot and cold water, bath, lavatory and telephone. All furniture is of walnut or African mahogany and is covered with cellulose, which can easily be washed, avoiding the need of polishing. While scrupulous attention has been given to hygiene, everything has been done to remove as far as possible the atmosphere of a hospital. It is believed that this must have an important psychologic effect on patients. There are no bells or buzzers. A patient wishing to call a nurse presses a button, and a colored light flashes out over the door in the corridor. The home has seven operating theaters, two labor wards on the maternity floor, a special theater for nose and throat patients, and a dental room. The theaters are installed on the eighth floor in order to secure absolute silence; each has a north light. The latest equipment has been installed for research and treatment—radium, x-rays high voltage roentgen therapy, actinotherapy, various forms of baths, and laboratories. Two resident medical officers have been appointed, and there will be a staff of 200 nurses. The thirty porters and attendants are all ex-service men, of whom four have been put through a course of intensive training in operating theater work at the London Hospital. The home will be available for the patients of all physicians, who can look after them and call in the services of a consultant with the same freedom as in any other nursing home; but the use of the operating theaters for major operations will be limited to surgeons on the staff of the great teaching hospitals. The cost of the buildings has been $2,000,000; of the furniture and equipment, $150,000.

The Jews in English Medicine

The prospects of Anglo-Jewry contributing leading scientists in the sphere of medicine, such as have appeared on the continent, were discussed at the annual dinner of the London Jewish Hospital Medical Society. Lord Moynihan, who was the guest of honor, said that the instrusion of the Jew into science had been a matter of great interest to him, for, after all, the striking thing about the Jew was not so much his zest for knowledge as his zeal for righteousness, and when that zeal was carried out, as it had been by many Jews of quite first rank in medicine and surgery, it had given to their practice a kind of intellectual integrity that he thought was quite distinctive. Dr. A. Goodman Levy said that it was remarkable that English Jews had so far failed to attain that degree of fame attained in medicine by their continental brethren. They had no men to compare with such famous names as Cohnheim, Ehrlich, Politzer, Nidal, Wassermann, Israel, Schiff, Haffkine, Besredka, Freud, Landsteiner and Baginsky. Was this due to the lack until recent years of a Jewish hospital in England?

A New Antidiphtheritic Serum

Dr. Marquézy has presented to the Academy of Medicine a new antidiphtheritic serum, which possesses curative properties superior to those of the existing serums. The new serum is prepared by injecting into horses a mixture of diphtheria toxin and antitoxic serum. The injections are made subcutaneously over a period of several weeks, the antitoxin at first predominating but then gradually diminishing and giving way to the pure toxin. The toxin utilized is derived simultaneously from strain 8 of Park and Williams and from bacilli isolated from the throats of subjects affected with malignant diphtheria. The serum is prepared not solely from the diphtheria toxin but also from living micro-organisms that are injected into the horse along with the toxin. It is therefore both antitoxic and antimicrobic. Before it is used on man, it is deprived of its proteins and then concentrated by means of the physicochemical technic of electro-osmosis. Its injection produces slight or no reactions. It has been employed by Dr. Marquézy in 200 cases of diphtheria observed in the Hôpital Trousseau from April, 1930, to November, 1931. The serum is supplied by the Clin Laboratories, in ampules containing 10 cc. and titrating from 5,000 to 10,000 antidiphtheria units. A cure was effected, in spite of some cardiac disorders and paralysis of the palatine velum, in all but eighteen cases of hypertoxic diphtheria which proved rebellious, no matter how large the doses given or the early nature of the injection, even when the false membranes had disappeared and the appearance of the throat was again normal. It seemed in these unfortunate cases that the toxin was present in enormous quantities from the start and was fixed early.

A Method for Demonstrating the Arterial System

The Academy of Medicine gave a warm reception to Prof. Pedro Belou of Buenos Aires, who came to present a collection of anatomic preparations constituting an important aid for the study of the arterial network of the body. This network is rendered visible in its finest ramifications and in all parts of the body, including the delicate regions of the nervous system and of the organs of sense. Belou employs the Spalteholz method to render the tissues absolutely transparent but injects first into the arterial network a gelatinous solution containing a carefully determined percentage of minium, which penetrates to the precapillary network. The examination of preparations is carried out by means of roentgenography and stereoscopy, which furnishes anatomic plates of a perfection surpassing anything heretofore accomplished. The Academy congratulated Professor Belou, who, moreover, in passing through Bordeaux had been so thoughtful as to present to the Faculté de médecine of that city a bronze plaquette, purchased with funds subscribed by the physicians and students of the Argentine Republic, in memory of Professor Testut, who was a French master of anatomy.

Treatment of Tuberculosis by the Finikoff Method

For several years a trial of the method of Professor Finikoff of Leningrad for the treatment of tuberculosis of the bones and joints has been carried on in the surgical department of Professor Delbet in Paris. The treatment consists in the use of iodine dissolved in cod liver oil and calcium salts. The experiment now appears to be sufficiently conclusive to justify Delbet in making a report to the Academy of Medicine. The statistics cover 160 cases, which produced 126 lasting cures, twenty-four notable ameliorations and only six failures. All these results have been obtained in grave cases in adults, and even in aged men, without any operation and without immobilization of the limbs. The cures have persisted from three to six years since the cessation of treatment in cases in which, for the most part, mutilating operations or permanent ankyloses would have inevitably resulted if the ordinary methods had been followed.

Attitude of Academy Toward Scientific Discoveries

The question of protection for scientific property, which was brought before the Academy of Medicine several months ago, has been considered with great care by a committee composed of Messieurs d'Arsonval, Hanriot, Bezançon, Léon Bernard and Madame Curie. The question involves a plan of protecting the property rights of scientists in their discoveries, just as the property rights of authors in their books have been recognized and protected. The question is not as simple as it appears. The question of property rights to scientific discoveries has only an academic interest until the discovery has had commercial applications. When that time comes, it is usually evident that such applications have as their point of departure not a single discovery of one scientist but the successive researches of many scientists and of different countries. The rights of the scientist would have no legal basis unless the scientist made an official declaration and took patents for each of his discoveries. There is, however, much that is likely to remain forever in the domain of pure science without any commercial application ever developing. In order to safeguard in the future a hypothetic property, a scientist during his whole career would thus be compelled to observe many expensive formalities, which for the most part would be of no intrinsic value. Scientists cannot all afford the luxury of 1,400 patents, as did Edison. The Academy received first a report from Madame Curie, who decided in favor of protecting the rights of the scientists. Mr. Fourneau, who holds patents for his dicovery of stovaine and its derivatives, unexpectedly raised objections that retarded somewhat the work of the committee. The committee, however, set aside the objections of Fourneau as foreign to the subject; for they centered about a vast plan for the reorganization of the work in the laboratory of the faculties of medicine, which he considered entirely too numerous and wished to see centralized in a much smaller number of laboratories with larger endowments. At the session of December 29, the Academy adopted the following resolution: "The Academy declares in favor of the recognition of the property rights of scientists and expresses the desire that the recognition of these rights be speedily proclaimed through the initiative of the public authorities." Recently the general assembly of the British Medical Association rendered just the opposite decision, having declared that it is contrary to the interests of the general public to restrict by any means whatever the use of a remedy or of any instrument or useful instrumentation. The French thesis, however, is that the levying of this tribute should be made on the commercial enterprises that make fortunes out of the research of scientists.

The Centenary of Félix Guyon

The hundredth anniversary of the birth of the French urologist Félix Guyon was commemorated by special ceremonies, held at the Academy of Medicine, of which Guyon was once president, and at the Hôpital Necker, where he created the first chair of clinical instruction in urology and where he taught for nearly forty years. Professor Legueu, who was a favorite pupil of Guyon and who now occupies Guyon's chair, delivered a eulogy on his teacher and traced the various stages in his career. In the audience were teachers of the Faculté de médecine, representatives of the university, the ministry of public instruction and ministry of public health, the director of the Assistance publique in Paris, and a large group of urologists who came from Paris, the provinces and foreign countries. Professor Hogge of Liége then spoke in the name of the foreign pupils of Guyon. Short addresses were delivered also by Professor Pousson of Bordeaux, Dr. Michon, Dr. Pasteau, Dr. Mirallié of Nantes, where Guyon began his studies, and Professor

Balthazard, dean of the Faculté de médecine. On this occasion the minister conferred on Professor Hogge the insignia of an officer of the Legion of Honor.

Death of Professor Rémond

The death of Professor Rémond of Toulouse, at the age of 68, is announced. Professor Rémond was born at Metz and studied medicine in Nancy, and later in Paris, where he became one of the most brilliant pupils of Professor Debove. He was appointed associate professor, and later professor, of the clinical aspects of mental diseases, at the Faculté de médecine in Toulouse. He was the author of many works dealing with his specialty. He published a "Manual of Mental Diseases," which is a classic in France, and also a French translation of the large treatise of Kraft-Ebing.

ITALY

Dec. 15, 1931.

Congress of Internal Medicine

The Società italiana di medicina interna held recently its thirty-seventh national congress in Bari. Prof. Francesco Galdi, director of the Clinica medica of the Università Adriatica, was chairman of the committee on organization.

DIABETES

Prof. Luigi Zoia of Milan, who presented a paper on diabetes, first considered the meaning of the regulation of exchange, regulatory centers, harmonic equilibrium and vegetative tonus. The endocrine glands have a functional tonus independent of one another; yet the resultant of their action is determined by their mutual influence on one another. This mutual influence is observable also with reference to the suprarenal glands and the islands of Langerhans, which function correlatively but each one according to its own proper tonus, which clearly appears especially under pathologic conditions. The particular chemicophysical constitution of the protoplasm of every individual determines the tonus of the neurovegetative system and of the endocrine glands. The most important examination in the presence of glycosuria is the determination of the blood sugar. There may be glycosuria with normal blood sugar (renal diabetes of Klemperer) or glycosuria with hyperglycemia, the most common example of which is pancreatic diabetes. These two forms are frankly distinct in their clinical course and their indicated treatment. In glycosuria with normal blood sugar, no notable alimentary restrictions are imposed nor is insulin treatment employed. The treatment of glycosuria with hyperglycemia is based, however, on the restricted diet and on the administration of insulin. In glycosuria with normal blood sugar not only is the glycemic curve with reference to sugar normal but also the Delpish and Hasenhörl, the Staub and the Radoslaw tests are normal. The renal threshold for sugar depends on the peculiar qualities of the individual. It is lower in persons with an increased vagal tonus but higher in persons with a high tonus of the sympathetic nerve. It has not yet been ascertained whether in the blood and in the organism in general dextrose exists also in the form of active dextrose. It probably exists also in a hydrolyzable form and there are doubtless saccharoids. These bodies deserve to be studied later more carefully. The glycemic curve with reference to dextrose throws great light on the types of diabetes. It is not clear whether the reason for the condition is to be sought in a demobilization of the dextrose of the liver due to a reflex action of the digestive tract or to the effects of epinephrine. It has, however, been shown that it is possibly due to the absorption of dextrose ingested by mouth. In diabetic patients the elimination of bilinogen is below normal and is not in relation to a torpid hemoglobin exchange. The treatment of choice in diabetes mellitus is a combination of a restricted diet and insulin therapy. The diet should resemble as far as possible the diet that would be physiologic for a given patient if he were not diabetic. If, on the prescribed diet, the patient eliminates sugar, a further reduction of the carbohydrates should not be resorted to, as this might lead to an acidosis or to disturbances of the kidneys, the liver or the heart, owing to the consequently necessary increase of fats and proteins; but one must modify the defective assimilation of carbohydrates by means of insulin. In order to prevent the appearance of ketone bodies, the quantity of protein substances ingested daily should not exceed 1 Gm. for each kilogram of body weight of the patient. The appearance of symptoms of hypoglycemia is due to an inaccurate prescription as to diet and insulin doses and should be corrected at once. The surgical treatment of diabetes has not given thus far very practical results. In the discussion that followed, Ascoli of Palermo remarked that the discovery of insulin has not solved the problem of diabetes, which, moreover, does not concern solely the pancreas. He recalled the pluriglandular conception and the nervous theory, held in Italy by Cesa-Bianchi. It is the task of the modern physician to discover diabetes before glycosuria manifests itself, by means of the sugar content of the blood. For the treatment it would be well to establish ambulatoriums for antidiabetic treatment. Condorelli of Naples reported on his experimental researches on dextrose excreted by the liver in diabetic patients as a result of nervous reflexes. D'Amato of Naples by clinical researches was able to show that by means of suitable modification of diet one can save the loss of nitrogen in emaciated diabetic patients. He thinks that also in grave diabetes loss of nitrogen can be prevented. Cesa-Bianchi of Milan brought out that in the genesis of hyperglycemic diabetes other neuro-endocrine syndromes besides that affecting the pancreas are involved. He thinks that the liver has been neglected and that possibly some day the classic conception of Claude Bernard will be revived. Ferranini of Catania emphasized the need of seeking other therapeutic aids, in order to help the diabetic; for example, he believes in the usefulness of sulphurous waters. After Professor Frugoni, clinician of Rome, had surveyed the discussion and pointed out that, although there are still obscure points, much has been accomplished in the study of diabetes, Professor Zoia responded to the questioners.

ORIGIN AND CLINICAL EVOLUTION OF TUBERCULOSIS

The second official topic, "Mode of Origin and Clinical Evolution of Pulmonary Tuberculosis," was presented by Prof. Carlo Gamna of Siena and Professor Omodei-Zorini of Rome. Gamna defined the form and the significance of the first lesions that follow the primary infection and illustrated in turn the various modes of evolution of the postprimary clinical manifestations, particularly isolated tuberculosis of the apex, which, in the nosographic sense, presents a rather peculiar and characteristic aspect; then the nonapical circumscribed chronic types, which represent, to a great extent, chronic evolutive stages of early infiltrates or hematogenopulmonary metastases of slow evolution. Gamna then described the infiltrated lesions, which are usually extra-apical, of which the early subclavicular infiltrate of Assmann and Redeker is a type. He expounded the pathogenic and clinical problems connected herewith, on account of which the whole study of phthisiogenesis is being revamped on a modern basis. He took up then the intrapulmonary diffusion of the disease and finally considered the conditions and factors that influence the development of pulmonary tuberculosis —the organic constitution, the age, the functions of maternity, diabetes, cancer, and the like.

Professor Omodei-Zorini presented the official paper on the second half of the subject. The speaker confirmed, on the basis of experimental, morphologic data and statistics collected in recent decades, the rare pathogenic action of the bovine bacillus on the human lung, the old hypothesis of Behring notwithstanding. He emphasized that no practical importance attaches to bacilli of the avian type or of cold-blooded animals, or to saprophytic acid-resistant bacilli. The speaker gave then a critical résumé of the theory of the granular and filtrable types of virus, reviewing the objections to the filtrability of the bacillus. Omodei-Zorini opposed the theory of the transplacental passage of the filtrable virus and of its pathogenicity for the organism of the new-born and of the nursling. The speaker assigned the greatest importance to extra-uterine contagion, citing, among the more common sources of infection, bacilliferous dust, the direct inhalation of bacillary material and its penetration into the bronchioles and into the alveoli of children during infancy and early childhood. He ascribes the highest defensive value to the upper air passages, which may, however, be disturbed by inflammatory processes and exanthematic infectious diseases. In such manner there occurs (at least once in the lifetime of most persons) the intrapulmonary penetration of bacillary material sufficient to cause a circumscribed tuberculous process.

The discussion that followed was participated in by Professor Giuffrè of Palermo, who emphasized that radiologic research on pulmonary tuberculosis should remain under the control of the clinic and should not tend to become a separate branch. Terni of Naples called attention to the importance of the researches of Ninni and of Sanarelli on the tuberculous ultravirus. Prof. Edoardo Maragliano, senator, delivered a lecture on the scientific bases of preventive antituberculosis vaccination in man.

RELATIONS BETWEEN MALARIA AND TUBERCULOSIS

The official speaker for the fourth topic, "The Relations Between Malaria and Tuberculosis," was Dr. De Bernardinis, lieutenant colonel of the army medical corps, who pointed out that of the arguments adduced in favor of the antagonism between malaria and tuberculosis some have only historical interest. No practical value attaches to the announcements preceding the discoveries of Laveran and Koch in regard to the specific agents of the two infections. Tuberculosis is variously diffused throughout the world but in general, to a greater rather than to a less extent, in the malarial zones. In Europe the lowest mortality rates from tuberculosis are reported from countries where there is little malaria, such as Denmark and England, while the highest mortality rates from tuberculosis are recorded in countries in which malaria infection abounds, such as Bulgaria and Greece. In the Italian army, of the men enlisted from the department of Cagliari (Sardinia), 11.57 per thousand were eliminated in one year owing to various types of tuberculosis or pretuberculous conditions, whereas in the department of Turin, where there is no malaria, the proportion was only 4.53 per thousand. The speaker thinks it would be well to extend his researches also to the relations between malaria and tuberculosis, on the one hand, and other concomitant diseases, such as syphilis, diabetes, leukemia, cancer and typhoid. An inquiry carried out in the Italian military hospitals showed that, in 135 out of 680 cases of tuberculous lesions of the lungs in soldiers affected with malaria, it was due solely to the malaria that specific signs of tuberculosis were brought out in a number of robust and otherwise healthy subjects, which had not been previously revealed; hence, the speaker regarded as proved the thesis that malaria may assume the rôle of revealer of pulmonary tuberculosis.

In the discussion, Professor Galdi of Bari stated that he had observed that in Sardinia, where malaria is widespread, there is also a high percentage of tuberculosis. Pozzilli of Rome proposed the creation in the military sanatoriums of a department for tuberculous patients in which special emphasis could be placed, in the taking of the personal history, on the possible existence of a previous malaria. De Bernardinis responded to all questioners. Rome was selected as the meeting place for the next congress.

Proposed Reforms in the Medical Curriculum

The medical curriculum of Germany continues to be a subject of considerable controversy. The aims sought are a more suitable presentation of instruction in science, a better practical training, and, at the same time, a certain checking of the afflux of medical students. The deliberations in the federal ministry of the interior, in which representatives of the provincial governments, the federations of the German faculties of medicine, the medical profession, and the medical student body, participated, concerned chiefly the preclinical years. The reforms in the clinical studies will be considered later in connection with the introduction of the new provisions with regard to the premedical examination. In the recent deliberations the central prevailing idea was that ways and means must be found to exclude as early as possible unsuitable elements from the study of medicine. As a means to that end, it was suggested that the premedical examination be made up of two parts, one dealing with the natural sciences, in the narrower sense, and one with anatomy and physiology. Likewise, the rules governing the passing of examinations, particularly as regards opportunities for repetition, should be made more rigid. Whether or not it will be necessary to lengthen the number of years required in residence is not yet certain. New provisions affecting the premedical examination are being worked out in the federal ministry of the interior. These provisions may go into effect at the beginning of the next summer semester.

Professor von Noorden's Golden Jubilee

Prof. Carl von Noorden of Vienna, well known as a clinician and for his work on metabolism, celebrated, December 28, the fiftieth anniversary of his graduation as a doctor of medicine. Von Noorden, a pupil of the physiologist Viktor Hensen in Kiel and of the clinicians Riegel in Giessen and Karl Gerhardt in Berlin, developed a great activity as a scientific investigator and teacher, while serving as an assistant physician at the Charité Hospital in Berlin. In connection with many different diseases he stimulated his pupils to make researches on metabolism. In his large work "Pathologie des Stoffwechsels," published later, he made use of a large number of researches that were carried out in his department in Berlin. In 1894, von Noorden removed to Frankfort-on-Main, as the head physician of the department of internal medicine in the Municipal Hospital. In 1906, he became the successor of Nothnagel in Vienna, but returned in 1913 to Frankfort, where he received an appointment as an honorary ordinarius. Since 1929, von Noorden has served as consultant in diseases of metabolism at the municipal hospitals and as the director of a special department for diseases characterized by a disturbance of sugar metabolism. His work on diabetes, which first appeared a generation ago and has passed through many editions, has been regarded in Germany, as well as in foreign countries, as a fundamental treatise on the subject. Also his work "Klinik der Darmkrankheiten" has received great attention. Von Noorden has an international reputation in the field of diseases of metabolism, particularly diabetes.

Professor Moritz Honored

Likewise, Prof. Friedrich Moritz, who was, for many years, ordinarius for internal medicine at the University of Cologne, celebrated, December 10, his seventieth birthday. Moritz has been trail blazer in many fields of internal medicine. He is the inventor of the orthodiagraph, which enables the examiner to record without perspective errors the true form and size of roentgen pictures thrown on a screen. This invention has been the point of departure of numerous researches on heart diagnosis. In collaboration with his pupil Tabora, he proposed a much used method for the determination of venous pressure. He prepared for Krehl and Marchand's "Handbook of General Pathology" the chapter on the dynamics of the heart and valvular defects. With the aid of Moritz's circulation model, the most important manifestations of the blood circulation can be clearly demonstrated. Toward the end of the last century Moritz emphasized the need of better instruction in dietetics. His book "Grundzüge der Krankenernährung" dates back to this period. The world of athletics and sport owes to Moritz and his pupils many researches carried out at a time when it was not a common thing to consider the influence of physical exercise on the body. In 1896, Moritz published a critical article on the licensing of specialists, in which, at that early day, he warned against the dangers resulting from overspecialization. In a brochure on "Psychographie des Mediziners und des Geisteswissenschaftlers," he endeavored to describe the aptitudes possessed by the true medical man. His scientific career led him from Munich, where he became a professor in 1890 and, as extraordinarius, conducted the policlinic in the Reisingerianum, by way of Greifswald, Giessen and Strasbourg, in 1911, to Cologne.

Death of Prof. Eduard Kaufmann

The death of Prof. Eduard Kaufmann, formerly ordinarius in pathology at the University of Göttingen, at the age of 72, is announced. Professor Kaufmann entered on his university career at the University of Breslau, in 1888. He later accepted a call to Basel, whence he removed, in 1907, to Göttingen. One important publication deals with his researches on tumors of the prostate. His chief work, however, is his textbook on special pathologic anatomy, which passed through ten editions and has been translated into five languages. Aside from the large handbooks on the subject, this work is the most comprehensive in the German literature. Herein an eminent investigator surveys his entire field of research. Kaufmann considered this publication as the best expression of his life work.

RIO DE JANEIRO

(From Our Regular Correspondent)

Jan. 15, 1932.

Therapeutic Pneumopericardium in Carditis with Effusion

Addressing recently the Sociedade de Medicina e Cirurgia of Rio de Janeiro, Dr. N. Romano of Buenos Aires considered the favorable effects of therapeutic pneumopericardium on carditis with large effusions. The speaker has resorted to this treatment with good results for ten years. Therapeutic pneumopericardium prevents the formation of cardiac adhesions and favors the action of the heart. The necessary instruments to perform the operation are a needle 7 cm. long, a syringe of 20 cc. capacity with which the fluid of the effusion is removed, and a simple apparatus for production of pneumothorax. The amount of fluid removed should be replaced by the same amount of injected air, without exceeding, however, 400 cc. The point at which the puncture should be made is previously determined according to the amount of the effusion as shown by both the clinical and the roentgen examination. Whenever the operation is made in adults the speaker performs the puncture, as a rule, in either the fifth intercostal or the left parasternal space. When the operation is made in children, he performs the puncture according to Marfan's method at the subxiphoid point.

Transmission of Rat-Bite Fever to Guinea-Pigs

Dr. E. de Araujo, head of the laboratories of the Faculty of Medicine of Bahia and director of the Instituto Oswaldo Cruz, published recently an article on experimental diagnosis of rat-bite fever. He succeeded in transmitting the infection from a patient, aged 1 year, with a clinical diagnosis of rat-bite fever, to guinea-pigs, by means of the following experiments: Mice, whose blood had been previously examined to rule out the presence of spirilla, were inoculated with blood taken from the patient during the febrile period of the disease. Blood passages were subsequently made into guinea-pigs, one of which presented the picture of experimental rat-bite fever (falling of the hair and loss of weight). The animal died one month later. A motile micro-organism, morphologically similar to that described by Carter in 1887 under the name of Spirillum minus, was isolated from the blood of all guinea-pigs that were inoculated. The speaker said that Bergey classed Spirillum minus as a genus of Borrelia belonging to the order of Spirochaetaceae. Weyton and also Bergey and his collaborators identified the micro-organism as Borrelia muris, a special variety of Borrelia. Lehmann and Neumann classified the genus as Spirilla. During the speaker's experiments the intratesticular inoculation into the guinea-pigs was followed by an inflammatory reaction in the testicles. The fluid obtained by a puncture of the swollen testicles contained a large number of spirochetes and the examination of the blood for the micro-organism gave positive results. The speaker believes that the bacteria isolated in his experiments is the same found by several authors in cases of rat-bite fever, although the strain in his cases did not cause death of the infected animals. The speaker reviewed the seven cases of rat-bite fever previously reported in Brazil: C. Chagas and Gomes de Faria reported one case each, in Rio de Janeiro, in 1915 and in Curityba in 1919, respectively; H. C. de Souza Araujo and C. Pinto reported one case in Curityba in 1919, and Gomes de Faría and A. da Matta reported two cases each in Rio de Janeiro in 1915 and in Manáos in 1920, respectively. In all the seven cases the diagnosis was made by Fontana's method. Spirochetes were isolated from the urine sediment in six cases and from the fluid obtained by puncture of a lymph gland in one case. The speaker's case is the eighth case of rat-bite fever reported in Brazil and the first one in which the experimental inoculation gave positive results.

Clinical Diagnosis of Acidosis

Dr. T. de Azevedo of Bahia recently published an article in which he studies the possibility of making a clinical diagnosis of acidosis by the symptoms described by several authors, especially Prof. Annes Dias of Porto Alegre. The presence of two symptoms (saccharomycosis buccalis and frequent sobbing) is a constant characteristic in the several clinical forms of acidosis which Annes Dias differentiated into acidosis of respiratory, nervous, siderant, cardiac, digestive and peritoneal types. The speaker reported a case in a child, aged 3, in whom the clinical diagnosis was made without examining the patient, who was at a great distance from the city. The clinical diagnosis was made through the description of the symptoms as given by the patient's father, who said that the patient had painful and distended abdomen and frequent sobbing and yawning. The administration of sodium bicarbonate and sodium citrate by oral and rectal routes was followed by the recovery of the patient within forty-eight hours.

Marriages

Charan Singh Sandhu, Amrit Sar, Punjab, India, to Miss Helen Olive Gregg of Cleveland, in Newport, Ky., February 3.

Haldor Barnes, Whitehall, Mich., to Miss Phyllis Creig of New Plymouth, New Zealand, in Detroit, January 9.

Percy Gatling Hamlin, Philadelphia, to Miss Elizabeth Beverly Scott of Williamsburg, Va., February 6.

Deaths

Verner Simpson Gaggin, Pittsburgh; New York Homeopathic Medical College and Hospital, 1895; member of the Medical Society of the State of Pennsylvania; served during the World War; on the staff of the Homeopathic Medical and Surgical Hospital; aged 62; died, January 22, of coronary sclerosis.

Thomas Warren De Hass, Indianapolis; Medical College of Ohio, Cincinnati, 1883; Bellevue Hospital Medical College, New York, 1888; formerly assistant professor of medicine, Indiana University School of Medicine; for many years on the staff of the City Hospital; aged 75; died, January 25, of heart disease.

David Israel Frankel ⊕ Boston; Boston University School of Medicine, 1916; instructor in clinical surgery and tropical diseases at his alma mater; fellow of the American College of Surgeons; assistant visiting surgeon to the Massachusetts Memorial Hospitals; aged 47; died, January 23, of heart disease.

William Edward Campbell, Sr., Atlanta, Ga.; Medical Department of the University of the City of New York, 1888; member of the American Laryngological, Rhinological and Otological Society and fellow of the American College of Surgeons; aged 66; died, January 7, of myocarditis.

Giles Burneston Cook, Front Royal, Va.; Columbian University Medical Department, Washington, D. C., 1903; member of the Medical Society of Virginia; served during the World War; aged 54; died, January 2, in the Walter Reed General Hospital, Washington, D. C., of adenocarcinoma.

David Edwin McMaster, Tennille, Ga.; University of Georgia Medical Department, Augusta, 1886; member of the Medical Association of Georgia; past president of the Washington County Medical Society; aged 71; died, January 8, of heart disease, nephritis and arteriosclerosis.

Clamor Henry Magna, Jr. ⊕ Brooklyn; Columbia University College of Physicians and Surgeons, New York, 1918; superintendent of the Kings County Hospital; aged 36; was found dead, January 27, in a hotel at Portsmouth, N. H., of self-inflicted incised wounds of the wrists.

John Andrew Morrisey, Newark, N. Y.; University of Michigan Medical School, Ann Arbor, 1895; member of the Medical Society of the State of New York; aged 64; died, January 8, in the Clifton Springs (N. Y.) Sanitarium, following an *operation for carcinoma of the colon.*

Patrick K. Mullany, Gary, Ind.; Schools of Surgery, Royal College of Surgeons in Ireland, Dublin, Ireland, 1906; member of the Indiana State Medical Association; aged 50; died, January 10, in the Mercy Hospital, of acute appendicitis and streptococcic peritonitis.

William Lewis Rhonehouse, Toledo, Ohio; University of Michigan Homeopathic Medical School, Ann Arbor, 1910; member of the board of education of Maumee; aged 45; was killed, January 6, when the automobile in which he was driving was struck by an interurban car.

Crowell Clarinton Hall, Hartford, Conn.; Johns Hopkins University School of Medicine, Baltimore, 1910; member of the Connecticut State Medical Society; served during the World War; aged 47; died, January 25, of meningitis following a sinus infection.

Sherman Russell Lancaster, Cambridge, Mass.; Medical Department of the University of the City of New York, 1887; member of the Massachusetts Medical Society; aged 70; died, January 26, in the Westboro (Mass.) State Hospital, of chronic myocarditis.

Alfred Herman Duerschner, Ray Brook, N. Y.; Albany Medical College, 1920; member of the Medical Society of the State of New York; aged 36; on the staff of the New York State Hospital, where he died, January 22, of pulmonary tuberculosis.

Decatur Poindexter Butler, McCall Creek, Miss.; Louisville (Ky.) Medical College, 1897; member of the Mississippi State Medical Association; state senator; aged 61; died, January 13, of injuries received in an automobile accident.

Henry J. Herman, Webster, S. D.; Medical College of Ohio, Cincinnati, 1891, member of the South Dakota State Medical Association; county health officer; aged 63; died, Dec. 30, 1931, in St. Luke's Hospital, Aberdeen.

Delbert Chester Fox, Kenton, Ohio; Starling-Ohio Medical College, Columbus, 1909; member of the Ohio State Medical Association; aged 48; died, January 18, of a cerebral hemorrhage, following an automobile accident.

Forbes Elliott Godfrey, Mimico, Ont., Canada; University of Toronto Faculty of Medicine, 1889; formerly minister of health and labor in the Ontario provincial legislature; aged 63; died, January 6, of pernicious anemia.

Frederick Charles Low, High Bridge, N. J.; University of Pennsylvania School of Medicine, Philadelphia, 1894; member of the Medical Society of New Jersey; aged 64; died, February 2, of poison, self-administered.

Walter E. Edwards ⊕ Polk City, Fla.; Baltimore Medical College, 1896; aged 63; died, January 8, in the Morrell Memorial Hospital, Lakeland, of hypostatic pneumonia, cerebral hemorrhage and arteriosclerosis.

Thorvald Holen, Minneapolis; Medical Department of Hamline University, Minneapolis, 1902; member of the Minnesota State Medical Association; aged 57; died, January 12, of coronary arteriosclerosis.

Looney McCormack, Harrisburg, Ill.; St. Louis College of Physicians and Surgeons, 1898; member of the Illinois State Medical Society; aged 66; died, January 6, in the Lightner Hospital, of appendicitis.

Daniel Tillett Henderson, Macon, Ga.; Atlanta Medical College, 1914; member of the Medical Association of Georgia; on the staff of the Macon Hospital; aged 44; died, Dec. 31, 1931, of angina pectoris.

Luke Pryor Allison, Brownwood, Texas; Beaumont Hospital Medical College, St. Louis, 1893; fellow of the American College of Surgeons; aged 60; died, January 7, of thrombosis of the mesenteric vein.

John Freeland, White Sulphur Springs, W. Va.; Bellevue Hospital Medical College, New York, 1894; aged 58; died, January 19, in the Johns Hopkins Hospital, Baltimore, of acute dilatation of the heart.

John Edgar Leemon, Middletown, N. Y.; Medical Department of the University of the City of New York, 1894; veteran of the Spanish-American War; aged 60; died, January 7, of cerebral hemorrhage.

Sylvan McElroy ⊕ Orlando, Fla.; University of Maryland School of Medicine, Baltimore, 1907; city health officer; on the staff of the Orange General Hospital; aged 48; died suddenly, January 1.

James Edwin Hair, Bridgeport, Conn.; Kansas City College of Medicine and Surgery, 1917; aged 68; died, Dec. 24, 1931, in the Bridgeport Hospital, of arteriosclerotic hypertensive heart disease.

James Gettus McCue ⊕ Silver City, Iowa; Louisville (Ky.) Medical College, 1891; past president and secretary of the Mills County Medical Society; aged 63; died, January 7, of heart disease.

George Windsor Hatch, Wilton, N. H.; Dartmouth Medical School, Hanover, 1880; member of the New Hampshire Medical Society; aged 76; died, January 10, of cerebral hemorrhage.

William J. McDowell, Scottdale, Pa.; Jefferson Medical College of Philadelphia, 1884; member of the Medical Society of the State of Pennsylvania; aged 71; died, Oct. 14, 1931, of myocarditis.

Freeman J. Scott, Rock Falls, Ill.; Hahnemann Medical College and Hospital, Chicago, 1888; health officer of Rock Falls; formerly member of the school board; aged 65; died, January 5.

George Samuel Brown, Edina, Mo.; St. Louis College of Physicians and Surgeons, 1892; member of the Missouri State Medical Association; aged 62; died, January 13, of arteriosclerosis.

John Halliday Gillespie, Flushing, N. Y.; McGill University Faculty of Medicine, Montreal, Que., Canada, 1911; aged 49; died, January 11, in St. John's Hospital, Long Island City.

Octavius Thorndike Howe, Boston; Harvard University Medical School, Boston, 1877; member of the Massachusetts Medical Society; aged 80; died, Dec. 27, 1931, of heart disease.

Charles W. Head, Windsor, Mo.; Missouri Medical College, St. Louis, 1877; member of the Missouri State Medical Association; aged 76; died, January 11, of cerebral hemorrhage.

Joseph Armand Bedard ⊕ Lynn, Mass.; Laval University Faculty of Medicine, Quebec, Que., 1890; on the staff of the Lynn Hospital; aged 65; died, January 26, of coronary sclerosis.

William T. Gillespie, Boaz, Ala.; Chattanooga Medical College, 1898; aged 67; died, January 13, in a hospital at Gadsden, following an operation for intestinal adhesions.

James Benjamin Abbitt, Norfolk, Va.; Medical College of Virginia, Richmond, 1901; member of the Medical Society of Virginia; aged 60; died, January 12, of heart disease.

Daniel J. MacIsaac, Chicago; Chicago Medical School, 1920; aged 42; died, January 1, in St. Luke's Hospital, of injuries received when he was struck by an automobile.

Clarence Province ⊕ Franklin, Ind.; Jefferson Medical College of Philadelphia, 1895; formerly member of the school board; aged 60; died, January 22, of heart disease.

Clark S. Fortney, Hundred, W. Va.; Maryland Medical College, Baltimore, 1905; member of the West Virginia State Medical Association; aged 62; died, Dec. 15, 1931.

Eugene Chellis Glover, Boston; Harvard University Medical School, Boston, 1928; aged 28; died, January 22, in the Boston City Hospital, of cyanogen poisoning.

Dudley Watson Day, Rockford, Ill.; Rush Medical College, Chicago, 1907; on the staff of the Rockford Hospital; aged 49; died, January 15, of heart disease.

John Charles McMichael, Windermere, Fla.; Medical Department of Ohio Wesleyan University, Cleveland, 1895; aged 66; died, January 20, of heart disease.

Edgar Nelson McGiffert ⊕ Duluth, Minn.; College of Physicians and Surgeons in the City of New York, 1886; aged 70; died, January 10, of coronary occlusion.

Robert La Fayette Neal, Hapeville, Ga.; Southern Medical College, Atlanta, 1886; aged 68; died, January 1, of myocarditis, endocarditis and cardiac asthma.

Thomas McG. Smith, Eutaw, Ala.; Kentucky School of Medicine, Louisville, 1907; aged 47; died, Dec. 29, 1931, of a self-inflicted bullet wound of the head.

Arthur Burtis Allen, Buffalo; State University of Iowa College of Medicine, Iowa City, 1886; aged 70; died, January 14, of carcinoma of the stomach.

Denison J. Higley, Grandview, Iowa; University of Michigan Medical School, Ann Arbor, 1882; aged 78; died, Nov. 24, 1931, of bronchopneumonia.

Frank Seymour Love, Newton, Texas; Jefferson Medical College of Philadelphia, 1887; aged 65; died, Dec. 27, 1931, of nephritis and heart disease.

Marcellus L. Halbert, Cincinnatus, N. Y.; Geneva (N. Y.) Medical College, 1872; aged 82; died, January 19, of myocarditis and acute nephritis.

Henry T. Trumbauer, Coopersburg, Pa.; Jefferson Medical College of Philadelphia, 1863; aged 93; died, January 2, of capillary bronchitis.

Arthur Benjamin Cullum ⊕ Chanute, Kan.; Kansas City Homeopathic Medical College, 1897; aged 67; died, January 24, of angina pectoris.

Allen P. McRee, Cottagegrove, Tenn. (licensed, Tennessee, 1889); aged 68; died, January 1, in the Wiggins Clinic, Paris, of heart disease.

Ethel Lynn Gray, Portland, Ore.; University of Oregon Medical School, Portland, 1899; aged 64; died, January 12, of heart disease.

Faustina Bush, Norwich, Vt.; College of Physicians and Surgeons, Boston, 1891; aged 76; died, January 5, of cerebral hemorrhage.

Stephen Edwin Cone ⊕ Cincinnati; Miami Medical College, Cincinnati, 1896; aged 64; died, January 19, of coronary thrombosis.

David F. Ingles, Wichita, Kan.; Medical College of Ohio, Cincinnati, 1881; aged 74; died, January 28, of hypostatic pneumonia.

Alan Gardner, Los Angeles; McGill University Faculty of Medicine, Montreal, Que., Canada, 1878; aged 75; died, Nov. 20, 1931.

Richard E. Clevenger, Lima, Ohio; Miami Medical College, Cincinnati, 1886; aged 73; died, January 16, of heart disease.

S. B. Neilson, Ladonia, Texas; Missouri Medical College, St. Louis, 1882; aged 78; died, Dec. 14, 1931, of pneumonia.

Eugenia Adelaide Hurd, Los Gatos, Calif.; Cooper Medical College, San Francisco, 1894; aged 85; died, Nov. 21, 1931.

Joseph R. Walker, Rogersville, Tenn.; Jefferson Medical College of Philadelphia, 1854; aged 100; died, Dec. 18, 1931.

Emanuel Cross Nolan, Mount Pulaski, Ill.; Rush Medical College, Chicago, 1878; aged 78; died, January 9.

Orin William Joslin, Banning, Calif.; Milwaukee Medical College, 1903; aged 56; died, Nov. 19, 1931.

"RENESOL" the 100% Efficient Epilepsy Remedy

Some of the numerous letter-heads used by Goldblatt and Goldberg in exploiting the epileptic. There were no laboratories. The business consisted in selling phenobarbital (luminal) at an exorbitant price under such names as "Phenoleptol," "Nurosol," "Renesol," "Nurone," etc.

The above are various trade names used by Charles Goldblatt and Maurice E. Goldberg in selling phenobarbital (luminal) at an exorbitant price and under various trade-marked names as a "cure" for epilepsy. Of course, the Messrs. Goldblatt and Goldberg are much too shrewd to declare frankly that their many-named nostrum is a "cure," but the whole trend of their advertising is such as to lead the public to believe that they have a cure.

Investigators report that the various named "laboratories" here listed are fakes; there are no laboratories. The address at 509 Fifth Avenue ("Nurosol Laboratories," now known as the "Renesol Laboratories") is merely a rented desk space from a real-estate brokerage concern that sublets desk space and mailing privileges to various concerns. The Vitosol Corporation is also a rented space in Suite 406, 489 Fifth Avenue, for which, according to a report of the Department of Health of the City of New York, Charles Goldblatt pays $5 a month.

Goldblatt and Goldberg, so far as investigation has been able to determine, have no chemical, pharmaceutical or medical knowledge. They certainly are not physicians and they are shrewd enough not to sell their stuff within the City of New

York, or they undoubtedly would be promptly arrested by the efficient officials of that city for violation of the law against unqualified practice.

It appears that Goldblatt and Goldberg hire a man who is legally licensed to call himself M.D., one Clarence J. Miner. According to our records, Dr. Miner was born in 1864, holds a diploma from the University of Minnesota College of Medicine and Surgery for 1891, and is licensed in Montana, Illinois, Kansas and New York. Miner was, for a while, an assistant surgeon at the Marion National Sanatorium in Indiana, but resigned in February, 1928. Miner's name appears frankly on the stationery of the Nurone Laboratories, Inc., as "Medical Adviser." In some of the advertising come-on material sent out by Goldblatt-Goldberg in connection with Renesol, there is a facsimile letter on Miner's personal stationery, puffing Renesol. Naturally, there is nothing to indicate to the public that receives this that Miner is an employee of the people that put out the stuff that he puffs.

Another testimonial for Renesol, used as part of the come-on literature by Goldblatt-Goldberg, is a letter on the stationery of one "Dr." Edwin F. Bowers, described on the stationery in which this puff appears as a "Specialist in Gland and Psychic Disorders," and who describes his methods as "Chiropractic and Physiotherapy." Edwin F. Bowers, according to the same piece of stationery, has his office at 642 South Berendo Street, Los Angeles. This is the same Edwin F. Bowers who, for many years, posed as an M.D., who contributed articles to *Physical Culture* in which he was labeled "M.D.," and who even went so far as to have printed stationery with the degree of "M.D." after his name, and who signed letters "Edwin F. Bowers, M.D."

This department of The Journal, some years ago, exposed the pretenses of Bowers, who has never been graduated by any reputable medical school. He used to work his game from the east, but after the Bureau of Investigation brought out the facts, he seems to have gone to Los Angeles. Where or how he acquired the title of "Doctor of Chiropractic," whether by correspondence or attendance, we do not know. Probably even the chiropractic colleges do not know. And even if he had a D.C. degree what would that have to do with the use of phenobarbital?

A testimonial for Phenoleptol, which is sent out as part of the advertising matter for that fake, purports to be from "A Prominent Florida Doctor," one "Dr. J. S. Riley, 359 Eighth Avenue, St. Petersburg, Fla." This seems to be none other than the redoubtable Joe Shelby Riley, who while he has claimed to be a graduate in medicine, is in fact, so far as our records show, not a graduate of any reputable medical school. Riley, at various times and in various places, has described himself as an M.D., and as a graduate in "Osteopathy, Naturopathy and Chiropractic." During 1913-1914, while Riley was in Boston as a chiropractor, it was reported that he was convicted and fined. He seems, first, to have appealed from the conviction but later to have changed his mind and paid the fine.

Riley, according to our records, was "president" of the "New England College of Chiropractics," a concern that was reported as having been found guilty of conferring diplomas illegally. After Massachusetts made it uncomfortable for him, Riley left that state and went to Washington, D. C. There, in 1920, he was using letterheads on which "J. Shelby Riley, Ph.D., LL.D., M.D., D.C., M.S., D.P.," was designated as "President" of the "National University of Therapeutics." This institution was described as "embodying and affiliated with the Universal College of Sciences, the National Phrenological Institute, the New England College of Chiropractic, the Washington School of Chiropractic." In 1921, Riley's letterheads declared him "President" of the "Riley School of Spinal Therapy (Successor to and Including the Washington School of Chiropractic)" of Washington, D. C. In 1928 and 1929, Riley was working the Cleveland, Ohio, field and distributing pamphlets on "The Cure of Deafness" and "Cancer, Its Cause and Eradication." In March, 1931, Joe Shelby Riley was advertising as an M.D. in the newspapers of St. Petersburg, Fla.

In advertising Nurosol, Vitosol, Phenoleptol and Renesol, quotations from medical literature are misused to make the public believe that scientific men have written in praise of these four nostrums, when, in fact, the quotations dealt with the substance phenobarbital. For instance, under Nurosol appeared this item:

> "Dr. Julius Grinker, Chicago, Ill., said in The Journal of the American Medical Association, it is the most effective remedy in the management of epilepsy . . ."

In the advertising of Vitosol and also of Renesol, there appears this statement:

> "In The Journal of the American Medical Association:—'It is the most effective remedy in the management of epilepsy . . .'"

In the Phenoleptol advertising we read:

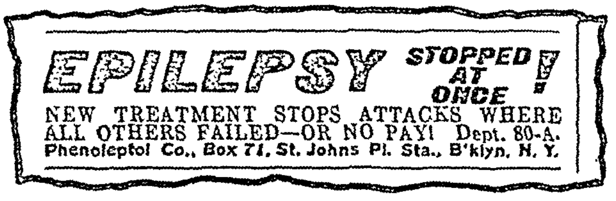
> "Prof. Julius Grinker: Journal of the American Medical Association. 'It is the most effective remedy in the management of epilepsy . . .'"

The facts are that the late Dr. Julius Grinker, in an article entitled "Further Experiences With Phenobarbital (Luminal) in Epilepsy" that appeared nine years ago (September 2, 1922) in The Journal of the American Medical Association, in summing up his opinion of the symptomatic use of phenobarbital in epilepsy, at that time, said:

"*Phenobarbital* is the most effective *symptomatic* remedy in the management of epilepsy."

In other words, Goldblatt and Goldberg have deleted the word "phenobarbital" and substituted the indefinite word "it," so as to make the quotation apply, respectively, to the nostrums they put out. They also have deleted, for their purpose, the important word "symptomatic" which Dr. Grinker naturally used in his statement.

The Messrs. Goldblatt and Goldberg even went so far as to drag in the name of the North Carolina State Colony for Epileptics, when, in advertising Renesol, they declared: "It is the *new remedy* which was used in the North Carolina State Colony for Epileptics. . . ." Dr. Albert Anderson, superintendent of that institution, wrote to the Renesol Laboratories, protesting against this misuse and received, in reply, a letter signed "L. Vollen," stating that the Renesol Laboratories were extremely sorry that the pamphlet containing this wholly false implication "has not yet been discontinued." They stated, further, that it would cause them considerable financial loss if they were required to destroy that particular pamphlet, but that if Dr. Anderson insisted on their doing so, they would destroy it. This was last November. In January, 1932, physicians were still sending in to the Bureau of Investigation some of the same Renesol pamphlets containing reference to the North Carolina institution.



EPILEPSY STOPPED AT ONCE!
NEW TREATMENT STOPS ATTACKS WHERE ALL OTHERS FAILED—OR NO PAY! Dept. 80-A.
Phenoleptol Co., Box 71, St. Johns Pl. Sta., B'klyn, N. Y.

An advertisement of one of the Goldblatt-Goldberg pieces of mail-order quackery.

Of all of the preparations put out by Goldblatt and Goldberg, Renesol seems to be the most widely advertised. Renesol used to be called "Nurosol," just as the Renesol Laboratories used to be called the "Nurosol Laboratories." Then, in 1929, they changed the name from Nurosol Laboratories to Renesol Laboratories, and the name "Nurosol" to "Renesol." In announcing this change, they made this statement:

> "We are very happy to announce the incorporation of a new ingredient into our Nurosol Remedy for Epilepsy sufferers. It took many years of experimenting to discover this ingredient, but we feel our efforts were fully rewarded. This addition gives our Nurosol Treatment greater therapeutic value. All the benefits of our old remedy can be obtained in a shorter period of time.
>
> "The new improved remedy with the added ingredient is known as renesol. This is the original Nurosol Treatment in which we have included the newly discovered ingredient which means *quicker* and more *certain relief* to all fit sufferers."

As Nurosol was advertised under exactly the same claims as Renesol is now advertised, with the same misleading quotations regarding phenobarbital (luminal)—with all reference to the drug itself deleted—one is justified in assuming that Nurosol was phenobarbital (luminal). Evidently, therefore, the "new ingredient" that Goldblatt-Goldberg claim to have incorporated into Nurosol, in order to make it Renesol, and which took "many years of experimenting to discover," is baking soda, as is shown below in the A. M. A. Chemical Laboratory's report. While numerous cursory tests have been made for some time past on specimens of Renesol that have been sent in by either physicians or laymen, no complete analysis had been made. For that reason, the Bureau of Investigation obtained an original "treatment" of Renesol direct from the Renesol concern. The medicaments were turned over to the A. M. A. Chemical Laboratory, whose report follows:

LABORATORY REPORT

"One original bottle of Renesol (The Renesol Laboratories, 509 Fifth Avenue, New York City) was submitted for examination to the A. M. A. Chemical Laboratory by the Bureau of Investigation. The bottle contained 65 pink capsules containing a white, odorless powder, possessing a mild alkaline taste.

"The average weight of the contents of ten (10) capsules was 0.0815 Gm. (approximately 1¼ grains) each. No statement concerning composition was given on the label, except: 'Contains no Bromides, Morphine, Opium or other Habit-forming Drugs.' (There was no accompanying circular received as stated on the label.) Microscopic examination indicated the presence of crystalline substances. Qualitative tests indicated the presence of a barbituric acid derivative, phenobarbital (Luminal), sodium and carbonate (presumably present as bicarbonate). Alkaloids, heavy metals, halides, sulphates, emodin-bearing drugs, lactose (milk-sugar) and starch were not found.

"Quantitative determinations yielded the following:

Phenobarbital	77.3 per cent
Sodium bicarbonate (baking soda)	23.1 per cent

"From the foregoing, it may be concluded that each capsule of 'Renesol—A Preparation for the Relief of Epilepsy' contains essentially 0.064 Gm. (approximately 1 grain) of phenobarbital, to which has been added a small quantity of sodium bicarbonate (baking soda)."

From this report, it is obvious that Renesol is essentially three-fourths phenobarbital (luminal) and one-fourth baking soda. One "treatment" of Renesol consists of 65 capsules, each containing approximately 1 grain of phenobarbital to the capsule. The company charges $4.50 for these 65 grains of phenobarbital, or, roughly, about seven cents a grain. Practically any retail druggist will put up phenobarbital in 1-grain capsules at not to exceed a cent and a half a grain. In other words, epileptics could purchase 65 1-grain phenobarbital capsules for less than a dollar, under no misapprehension as to the limitations—and dangers—of this substance. They pay $4.50 to the Goldblatt-Goldberg combination for the same stuff sold under various fancy names with no warning as to the products' potentialities for harm, and doubtless in the belief that the stuff will cure epilepsy.

Goldblatt and Goldberg have been carrying on this business now for some years under various misleading trade names; they have exploited a peculiarly unfortunate group, the epileptics, by selling at an exorbitant price, under false and misleading claims, a well-known drug that has no curative effect in the treatment of epilepsy; they have been doing this through the instrumentality of the United States mails. How much longer is the overworked fraud-order arm of the postal service going to allow Goldblatt and Goldberg to get away with it?

Mycosis Fungoides.—The condition familiarly known as mycosis fungoides is one of the most confused and confusing to be encountered in the domain of medicine. According to Fraser, at least nine different views have been advanced to explain its nature: that it is a granuloma; a cutaneous form of lymphadenoma; a lymphosarcoma; a condition midway between a granuloma and a sarcoma; an alymphemic lymphomatosis; a sarcoma engrafted on a previous dermatosis, as psoriasis or eczema; the last phase of a series of dermatoses that includes pityriasis rosea and the parapsoriases; a lymphoma of the skin, or, finally, the cutaneous manifestations of systemic disease.—Symmers, Douglas: Mycosis Fungoides as a Clinical and Pathologic Nonexistent, *Arch. Dermat. & Syph.* **25**:1 (Jan.) 1932.

REQUEST FOR OLD INSTRUMENTS FOR BENJAMIN FRANKLIN MEMORIAL

To the Editor:—We are preparing an exhibit of medical and surgical instruments, which we propose to house in the Benjamin Franklin Memorial and Franklin Institute Museum.

This institution, which we are building on the Parkway in Philadelphia, will doubtless be the world's greatest memorial to Benjamin Franklin. In addition to the memorial chamber, it will house all the activities of the old Franklin Institute and will contain also a modern museum of science and technology. We propose to install in the latter such a collection as we can make of surgical and medical instruments, both ancient and modern, which will show how the principles of physical science find application in the production of medical and surgical instruments.

It has occurred to us that there are, throughout the country, many physicians who would be interested in such a project and who would be willing either to donate, or to sell at low prices, old surgical or medical instruments. Any who are interested may send their names to Dr. Howard McClenahan, Secretary and Director, the Franklin Institute, 15 South Seventh Street, Philadelphia, Pa.

Howard McClenahan, Philadelphia.
Secretary and Director,
the Franklin Institute.

NUTRITIONAL ANEMIA

To the Editor:—I was of course interested in the editorial on nutritional anemia in The Journal, January 23. It is but natural that one not close to the details of this field would be left in confusion by the mass of material appearing in print from various sources. The work of Beard and Myers has added to the confusion. But that confusion will disappear in your own mind, I am sure, if you will turn to page 74 of the November, 1931, issue of the *Journal of Biological Chemistry*, in which their series of articles appear. Under the caption "Milk Used" you will read that the milk that they used was *"poured through about five feet of copper pipe into a large nickel cooler"* and that this milk contained 0.44 mg. of copper per liter.

It is of course obvious that one cannot demonstrate the supplementary relation of copper to iron when he starts his experiments with a milk that has been prepared by pouring through copper pipe and contains as much copper as their milk did. Experimental animals made anemic on that kind of a milk of course correct their anemia by the addition of iron only because there is already sufficient copper in the milk to meet the supplementary needs.

Keil and Nelson (*Proc. Soc. Exper. Biol. & Med.* **28**:392 [Jan.] 1931; *J. Biol. Chem.* **93**:49 [Sept.] 1931) experienced exactly the same trouble that Beard and Myers did in trying to demonstrate the supplementary relation of copper. They first worked with a milk containing 0.44 mg. of copper per liter, and of course could not demonstrate the needs of copper. After further correction of their technic of securing the milk in clean glass bottles, thereby obtaining milk with a copper content of about 0.23 mg. per liter, they were able fully to substantiate all of our work.

It is only fair to state that in the article of Beard and Myers referred to, they state that "in experiments with rats 196 to 256 the milk never came in contact with any metal containers." However, they give no estimation of the copper content of that milk, and their published records show that it was never used with iron as the only supplement but only with iron and zinc; but whether the contamination might have been from zinc no one knows.

In my judgment the confusion about nutritional anemia does lie, as you say, in the local factors; but these local factors are not mysterious factors at all. They are factors of deviation from a sound experimental technic which involves not only the source and handling of the milk but also the time of weaning of the young, and whether the young are left in contact with the ordinary ration or are handled in such a way as to prevent their securing grain food during the suckling stage. In the February issue of the *Journal of Biological Chemistry* we shall discuss the matter fully.

E. B. Hart, B.S., Madison, Wis.

SENSITIZATION TO CHRYSANTHEMUMS

To the Editor:—In The Journal, January 16, page 251, I note an inquiry about sensitization to chrysanthemums. In the answer, stress was laid on the petals as the possible cause of the dermatitis.

At a meeting of the Chicago Society of Allergy, Dec. 21, 1931, I reported a case in which the petals gave negative patch tests and the leaves gave a positive reaction. The ether soluble fraction of the pulverized leaves contained the active agent.

In a report in The Journal, May 16, 1931, page 1680, Goldstein reported the leaves as responsible for chrysanthemum dermatitis.

I note that the inquiring physician resides in California and in this connection my patient informed me that the chrysanthemums causing his dermatitis came from that state.

Isadore Pilot, M.D., Chicago.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

ACIDOSIS

To the Editor:—There is so much confusion about the word acidosis that I want to ask your opinion. I have always considered acidosis to be due to incomplete combustion of fats (for instance, in diabetes) and that the lack of the correct proportion of fats is the cause. Another school maintains that there is a carbohydrate acidosis. What definition has this school for the word acidosis? If it is a different condition from that ordinarily called acidosis due to fat, the word is misused and there are two conditions bearing the same name. Is there evidence of an altered acid-alkali ratio in the blood on a carbohydrate diet? If not, why say acidosis? I think that "they" must be confusing the matter on account of the stressing by pediatricians of sugar fermentation in infants. Some claim that there is an acidosis in pellagra. Of course, pellagra is known to be a vitamin deficiency disease, but in what way can an acidosis be brought about? I have never paid any attention to the using of alkalis with pellagra. I feed yeast, and the like. In fact, there is an absence or a deficiency of hydrochloric acid in the stomach, and an anemic state is produced. I give hydrochloric acid and not alkalis. Out of all this discussion, is there really any foundation for this propaganda against carbohydrates other than merely that an excess of these and the abstinence from proteins and fats produce deficiency diseases or obesity? Will living on carbohydrates cause all the dangers claimed?

W. B. Palmer, M.D., Furman, Ala.

Answer.—Our correspondent is quite correct in referring to the confusion in the use of the word acidosis. In fact, it has come to have somewhat different implications, as applied by different persons. Many clinicians employ the term in reference to the production of abnormal organic acids in the body, as the result of the aberrant oxidation of fats—a condition more properly referred to as ketosis.

Peters and Van Slyke (Quantitative Clinical Chemistry, Baltimore, Williams & Wilkins Company, 1931, vol. 1) give the following description:

> The terms acidosis and alkalosis have been applied almost indifferently to two types of conditions: (1) states in which the bicarbonate content of the blood is altered; (2) states in which the true reaction or hydrogen ion concentration of the blood is abnormal. In most of the commoner, and therefore earlier recognized, types of acidosis, as bicarbonate falls the alkalinity of the blood also diminishes, while in alkalosis the two functions move together in the opposite direction. For this reason little confusion is usually produced by this undiscriminating use of the terms. However, conditions are recognized, and not infrequently encountered, in which a reduction of bicarbonate is associated with increased blood alkalinity and increase of bicarbonate with a diminished blood alkalinity. The occurrence of such conditions necessitates exact definition of acidosis and of alkalosis unless these terms are to be replaced entirely by some more exactly descriptive nomenclature, such as the one that is proposed in a subsequent section of this paper.
>
> Acidosis may be broadly defined as an abnormal condition caused by the accumulation in the body of an excess of acid or the loss from the body of alkali. The more common cause is accumulation of acid, that is, a state in which acids are formed or absorbed more rapidly than they are destroyed or eliminated. The process may be considered to have produced a state of acidosis when it has caused either the bicarbonate of the blood to fall or the hydrogen ion concentration to rise above the normal limits.
>
> Alkalosis may be similarly defined as an abnormal condition caused by the accumulation in the body of an excess of alkali or by the loss of acid. The effect of either alkali accumulation or acid loss is to increase the bicarbonate and usually to diminish the hydrogen ion concentration of the blood.
>
> The exceptions to the general rule that the bicarbonate content and hydrogen ion concentrations in the blood move in opposite directions (that is, bicarbonate and *p*H vary in the same direction) is found in conditions in which the acid of which there is an excess or deficiency is carbonic acid

In his new introduction to biochemistry, R. J. Williams (An Introduction to Biochemistry, New York, D. Van Nostrand Company, Inc., 1931) says:

> The production of aceto-acetic acid and β-hydroxy-butyric acid and their accumulations in the blood brings about a condition of acidosis in which the blood is less alkaline than normal. The alkaline reserve of the blood and tissues is drawn upon to neutralize these acids since the blood never becomes acid in reaction. These acids are then excreted by the kidneys in the form of salts, and this means a constant drain upon the sources of alkali in the body. The most important means which the body uses to prevent this drain is the formation and utilization of ammonia to neutralize the acidity. The ammonia arises from protein as will be noted in the following chapter. A condition of acidosis is accompanied by a high output of ammonia (in the form of ammonium salts) in the urine, and usually by the production of a highly acid urine. In cases of nephritis in which the kidneys are not functioning normally, there may be a condition of acidosis which is not accompanied by highly acid urine. In acidosis of this type, the condition may be due not to faulty utilization of fats, etc., but to the inability of the kidneys to excrete the acids which are continually formed in the course of normal metabolism.
>
> It may be noted that diabetic acidosis probably works in a vicious cycle, since improper utilization of carbohydrates leads to abnormal acid production, and the decreased alkalinity which results probably prevents normal metabolism of carbohydrates. The alkalinity of the blood is probably maintained in part at least to facilitate the oxidation of glucose. Administration of insulin to diabetics, which permits glucose utilization, results in alleviation of the acidosis.

The acidosis of diabetes, a high fat or ketogenic diet, or acute starvation is caused by the appearance of acetoacetic acid, beta-hydroxybutyric acid and the decomposition product, acetone, in the body. These substances arise when an insufficient amount of carbohydrate is available during the utilization of large amounts of fat. This condition is therefore only one particular form of acidosis and might perhaps better be referred to (from the chemical structure of these substances) as a ketosis.

The belief that there is a condition of acidosis in pellagra is based chiefly on older observations that there is an increased acid excretion in the urine in this condition. Recent investigations (Turner, Tulane University) tend to show that there is no great acid-base disturbance in pellagra but rather a decrease in the concentration of the serum electrolytes. It is interesting to note, however, that there have been recent reports of a pellagra-like skin lesion appearing in patients with ketosis.

MIGRAINE AND MENSTRUATION

To the Editor—A married woman, aged 45, suffers from severe migraine during her menstrual periods. She has never been pregnant. The menses began at 14 and have always been regular, occurring at thirty-day intervals; the flow has been normal and there have been no cramps at any time. The patient feels perfectly well until she begins to flow. At this time the headache comes on, and it is continuous until the end of the period, which is after five days Physical and laboratory examinations give negative results. The family history is also negative. I have tried many sedatives, even resorting to morphine, with little relief. I have given the patient two months' treatment with an endocrine product, which gave no relief. Then I had her treated with x-rays, as suggested by Kelly in The Journal, Sept. 12, 1931, for I hoped to obtain relief by causing a cessation of the menses. This was not successful, and the last period, which she has just finished, was as bad as the periods before treatment. I should appreciate any suggestions that you may make. Please omit name.

M.D., Washington.

Answer.—Unfortunately there is no specific treatment for migraine even when it is associated with the menstrual periods. In spite of Kelly's success, elimination of the menses will not cure all cases of migraine that occur during the monthly flow, because many women who have this type of headache continue to have it after the natural menopause as well as before it. In the case cited, the roentgen treatment did not stop the menses; hence one cannot tell whether castration by irradiation will or will not cure the migraine. Since the patient is 45, there will most likely be no harm in applying a sufficient dose of the roentgen rays to eliminate the menstrual flow entirely. While waiting for the effect of castration, and certainly if the irradiation is not helpful, it is important that the patient take special care to build up her resistance. She should have a well balanced diet and plenty of fluids; she should take a good deal of exercise, especially outdoors, and she should be sure to have a bowel movement at least once a day. If necessary, a tonic should be given. A careful examination should be made to detect any possible cause.

EPIPHORA

To the Editor:—A woman, aged 30, complains of epiphora of the left eye for several years. This is not constant but is worse when she is reading or under nervous tension, as when at a party. Her correction under cycloplegic is O. D. + 0.25 cyl. ax. 15; O. S. + 0.50 cyl. ax. 180. A man, aged 56, has had epiphora of the right eye only, for several years. This is worse in very bright light and when the patient is reading for only a short time, even though the light is properly placed and subdued His correction is O. D. + 2.75 S. = + 0.50 cyl. ax. 180, and O. S. + 3.50 S., which gives a vision of 6/6 + + + O. U. The reading addition is + 2.50. Both of these patients are in good general health. There is no history or evidence of allergy. Neither is subjected to irritating substances while at work. In each case the puncta are patent and in normal position, and the nasal duct is fully open. There is no evidence *of blepharitis, conjunctivitis, or inflammation of the lacrimal gland.* Any suggestions as to possible causes and corrections of this condition will be greatly appreciated. Please omit name and address.

M.D., Ohio.

Answer.—It is evident that in neither of these cases is the refractive error the causative factor of the annoying epiphora. But it is possible that there is an imbalance of the ocular muscles that may be contributory. The so-called nervous lacrimation is always bilateral and hence falls out of this picture. Another possibility is that the lacrimal puncta of the affected side do not dip into the lacrimal lake when the eyes converge for reading and, consequently, the tears cannot enter the tear passage. It is, of course, taken for granted that the possibility of a minute foreign body of the cornea or a small corneal infiltrate has been eliminated.

PREPARATION OF HANDS AND OF PATIENT PREVIOUS TO SURGICAL OPERATIONS

To the Editor:—For many years the technic of preparation of patients for abdominal operations and of sterilization of the surgeon's hands has remained unchanged at our institution. The question has been raised as to whether improvements may not be made in this technic for the mutual benefit of physician and patient. I should greatly appreciate it if you would answer the following questions: Do you have any criticism of our technic, which is as follows: The operative area is shaved. The patient's abdomen is scrubbed with liniment of soft soap and water, then washed with alcohol, and dried. Tincture of iodine, 3.5 per cent, is painted over the abdomen, which is then covered with a sterile towel. This is done in the ward or room several hours previous to the operation When the patient, under anesthesia, arrives in the operating room, the abdomen is again painted with 3.5 per cent iodine, and the iodine is wiped off with 95 per cent alcohol, after which the operative area is draped and the operation proceeds. The surgeon's hands are scrubbed for seven minutes with soap and water; while wet they are dipped in half strength tincture of iodine and then into 95 per cent alcohol, after which they are wiped dry on a sterile towel. The gown is put on, the hands are powdered and dry gloves put on. Do you feel that the iodine in the tincture is of any practical value, or will 95 per cent alcohol or a mixture of alcohol and acetone serve the same purpose? Do you think it practical to eliminate the preparation in the ward or room, and do the preparation of the patient in the anesthesia room just before operation? The literature on this subject is unsatisfactory, and I shall greatly appreciate a reply.

Harold A. Kazmann, M.D., Long Branch, N. J.

Answer.—For abdominal operations many different schemes have been employed for preparation of the patient, the surgeon and the assistants, and good results have been obtained by a number of different methods. The method that has stood the test of time and is probably the simplest and best method today is the following: The operative area is shaved and the patient is scrubbed with liniment of soft soap and water and then washed with 70 per cent alcohol. This is followed by a thorough washing for a minute or more with 1:2,000 corrosive mercuric chloride solution. The area is then dried and the field is ready for operation. This is done in the preparing room immediately before the operation. There are definite objections to the use of iodine. A few patients have an idiosyncrasy against iodine, and its use is followed by irritation and it is not nearly as efficient as the alcohol and mercuric chloride.

In regard to the surgeon's hands, this preparation has been much simplified and improved. The surgeon should wash his hands thoroughly with castile soap and warm water. If a brush is used it should not be a stiff brush but one that does not irritate the skin—a rather soft nail brush can be used to advantage. The hands should then be put in a 70 per cent solution of alcohol; the denatured alcohol employed is probably best (70 per cent alcohol, 1 per cent of phenol and 29 per cent water). The hands should be kept in this solution for about ninety seconds, then taken out and dried on a dry towel; sterile talcum powder should be poured on the hands and dry gloves should be used. In addition to this, a basin of mercuric chloride, 1:2,000, should be on hand so that after the surgeon has put on his gloves he can put them in the mercuric chloride solution and wash off the extra talcum, and then wash off the mercuric chloride solution in sterile water. All this preparation should be done immediately before the operation in the preparing room just before the patient is anesthetized.

This method has the sanction of Moynihan, who has done such brilliant surgery; of Harvey Cushing, one of the great leaders in brain surgery; of Lexer, who endorses it in the last edition of his Allgemeine Chirurgie, in which the subject of preparation is fully dealt with, and of Bevan at the Presbyterian Hospital, Chicago.

PURE WATER AND THE GOLDFISH TEST

To the Editor:—It has recently been noted that goldfish, when put into the drinking water that is used at this institution, die within a few hours. The water is pumped from a river into a settling basin and thence into a mixing vat in the filtering plant, where it is mixed with alum and lime; it then goes into another vat and is filtered through seven different grades of sand. About 85 thousand gallons of water is filtered daily with 115 pounds of alum and 50 pounds of lime. Please advise whether this water would be injurious to human beings and what process of filtration might be used to filter the water successfully so that there would be no possibility of any ill effects from its use. If you are unable to give this information I shall appreciate it if you will advise where specimens of this water may be sent for analysis. Any information you may give will be appreciated.

J. D. Riley, M.D., State Sanatorium, Ark.

Answer.—The removal of excessive color or turbidity from a water by the use of aluminum sulphate as a coagulant, often with the addition of lime to give a suitable degree of alkalinity, has long been known and widely practiced in this country and abroad. The quantity of the chemical agent to be used depends on the character of the water treated and is ordinarily determined by trial. The amount of coagulant generally used is between 0.03 and 0.13 Gm. (one-half and 2 grains) a gallon, but larger amounts are frequently used, particularly when rapid action is desired. The water should contain a residual alkalinity of at least 10 parts per million if it has been treated with aluminum sulphate or any other aluminum compound. No injurious effect on the consumer of such treated water has ever been recorded. The goldfish test of the potability of water is open to objection. Goldfish may die from a variety of causes, such as lack of oxygen in the water, which would not affect the wholesomeness of the water for human consumption.

TREATMENT OF DYSURIA

To the Editor:—Could you tell me the most reliable drugs or combination to use in old people (60 years of age) for frequent urination, burning and pain? I have three cases at present and have had several women, aged from 45 to 60. It lasts two or three weeks, and possibly a year or so later another attack occurs.

George C. Stimpson, M.D., Poysippi, Wis.

Answer.—The symptom complex "dysuria," frequent, burning and painful urination is indicative of bladder irritation and may be due to cystitis, pyelitis or pyelonephritis, ulcer, cancer or tuberculosis of the bladder. Obviously, treatment of the cause requires first consideration. If the condition is cystitis, its cause, whether urethral stricture, enlarged prostate or cystocele, needs to be determined, and, if it is removable, relapses will of course be prevented. The treatment of the cause having been attended to as well as possible, and cystitis being the presumable cause, either the alkaline or the acid treatment should be adopted, according to whether the freshly passed urine is alkaline or acid. If the urine is acid (B. coli-communis infection), alkalizing the urine often gives striking benefit, as with the use of the following prescription:

		Gm. or Cc.
℞	Tincture of hyoscyamus	30
	Potassium citrate	30
	Water	30
	Aromatic elixir	to make 120

M. Label: one or two teaspoonfuls in glassful of water every two hours.

When the urine is alkaline to start with, and in acid urine cases after several days of alkaline treatment, the urine is rendered acid, and this is combined with the administration of methenamine; for alkalis are not curative: they merely relieve the symptoms. This acid-methenamine treatment, on the other hand, often temporarily increases the discomfort; and the patient should be warned of this beforehand. The best drug for acidifying the urine is acid sodium phosphate given in doses of from 1 to 2 Gm. three times daily, the limit to which it may be pushed being determined by its laxative action. If necessary, ammonium benzoate (0.6 Gm. three times daily) may be used as an adjuvant. As soon as the urine has been acidified, methenamine may be given in initial doses of 0.3 Gm. three times daily, increased as rapidly as possible up to the point of tolerance, or from 1 to 1.3 Gm. three times daily. In obstinate cases with a chronic tendency, silver nitrate bladder instillations (from 1:10,000 up to 1:1,000) are likely to be useful.

CHRONIC INFLAMMATION IN GONORRHEA

To the Editor:—I should like to know the best treatment that you would advise for chronic gonorrhea and for a morning drop which returns after a rest of a period of months. Various silver preparations, autogenous vaccines and dilation of the urethra, followed by astringent irrigations of silver, have been used; I also made a urethroscopic and a cystoscopic examination to determine the pathologic condition, and I found none. I advised rest for three weeks or more, and the condition subsided for from one to several months, and again it returned. I have even inserted 2 to 3 per cent mercurochrome-220 soluble into the bladder. I get results from most of the methods used, but the condition seems to recur again, in some cases returning with a clear watery discharge producing no symptoms whatever. Microscopic examination shows a few pus cells and a few streptococci and staphylococci. The Wassermann tests give negative results. In the meantime, with no continuous discharge and no stricture, would you become suspicious that a malignant condition might develop after a number of years? One case gives a history of twenty years or more, is relieved for a certain length of time, and then recurs again. When the aforementioned treatments are used, I find that some of the patients are greatly relieved by intercourse. I shall appreciate any information you will suggest that will help bring about a lasting result. Please omit name.

M.D., Nebraska.

ANSWER.—Recurrence of a urethral discharge following gonorrheal processes may be based on the presence of follicular infiltrations, urethral strictures with submucous infiltration, chronic prostatitis and vesiculitis. Persistent inflammations of the urethral glands are diagnosed by urethroscopy and if the condition does not yield to dilation and instillations must be destroyed by galvanocaustic or the diathermic needle. Strictures are properly diagnosed and located by the use of olive-tipped sounds. This kind of instrumentation is of paramount importance in the so-called wide strictures. Submucous infiltrations underlying the cicatricial tissue are diagnosed by palpation over an introduced steel sound. The routine treatment of such conditions is systematic dilation and massage over the sound followed by injections of some disinfecting fluid. If, however, dilation is followed in short order by retraction, such observations indicate the presence of elastic fibers within the scar tissue, and a stricture of this character has to be treated by urethrotomy. Quite often the extended use of silver salts will maintain a discharge, and in such instances irrigations with indifferent solutions have to be resorted to. In practically all the chronic cases the posterior urethra, prostate and seminal vesicles are involved. Prostatitis and seminal vesiculitis are diagnosed by bimanual palpation and by expressing the contents of these organs immediately following cleansing of the urethra by irrigation. Prostatitis and vesiculitis are treated by systematic massage combined with medical diathermy and repeated intradermic injections of some protein. In some instances, so-called dead inert submucous urethral infiltrations are benefited by the use of the Oberlaender dilator. Unfortunately, chronic "catarrhal" afflictions of the urinary mucosa may recur in spite of all therapeutic efforts and have to be treated at intervals as often as the exigency arises.

TOBACCO IN ANGINA PECTORIS

To the Editor:—The authorities that I have been able to consult on the management of patients with angina pectoris say that the patient must abstain from the use of tobacco. Is it the opinion of those who have made a thorough study of angina pectoris and disease of the coronary arteries in general that absolute abstention from tobacco is essential in all such cases? Please omit name.

M.D., Ohio.

ANSWER.—Most authorities, as is stated in the query, advise that a patient with angina pectoris abstain from the use of tobacco. Not all physicians, however, mean by this that there should be absolute abstention. The consensus is that the excessive use of tobacco is harmful. This opinion is based merely on clinical experience, but it is so general that there is probably some foundation in fact for it. Some physicians go so far as to say that there is a type of angina that is due solely to tobacco, a "tobacco angina"; others do not recognize this as a peculiar form. To repeat, the prevailing opinion is that the excessive use of tobacco in any form, but chiefly in smoking, has an influence in increasing the number and severity of the paroxysms.

TREATMENT OF RINGWORM OF NAILS

To the Editor:—For four months I have been treating a case of ringworm of all the finger nails with the exception of one index finger, at first using 10 per cent sulphonated bitumen and ammoniated mercury ointment, and trichophytin hypodermically, and later a solution of chlorinated soda locally. Have you any other suggestions besides Whitfield's ointment? Please omit name.

M.D., Virginia.

ANSWER.—Ringworm of the nail is the most difficult form of the disease to cure. Fractional doses of roentgen rays may be given, one-fourth erythema dose each week for from eight to ten weeks. Strong antiseptic applications should not be used with this treatment. The rest of the finger should be shielded and each nail treated separately. If this fails, or in place of it, the nail may be softened by a wet dressing of Fehling's alkaline copper solution for two days; the soft nail should then be removed and the finger dressed with 2 per cent solution of copper sulphate, 25 per cent sodium thiosulphate, or a strong solution, from 0.25 to 1 per cent, of corrosive mercuric chloride in 50 per cent alcohol. The latter should not be used longer than twenty-four hours.

USE OF REFRACTOMETERS

To the Editor:—I wish to obtain information as to the value of the Rodenstock nonreflecting prism refractometer, which is made by Rodenstock of Munich, Germany, and has as its distributor in the United States the Independent Traders, Inc., of 11 West Forty-Second Street, New York. Is it of value in the armamentarium of the oculist? Does it, as it is claimed, replace retinoscopy and homatropine? Please omit name.

M.D., New York.

ANSWER.—The Rodenstock refractometer is as good an instrument of its kind as there is on the market, and as much can be accomplished with it as with any mechanical instrument for refraction. It does not replace a mydriatic, for it does not overcome accommodation. With a mydriatic it is just about as accurate as retinoscopy, either spherical or cylindric, and requires about the same amount of time. Without a mydriatic, no more accurate refractive results can be obtained than with the ordinary trial case. Thus far no refractometer has supplanted the usual time honored methods of refraction or added to the accuracy or speed.

OPIUM IN SUPPOSITORIES

To the Editor.—In suppositories for relief of hemorrhoidal pain, why is opium, which does not exert a local anodyne action, usually the drug of choice in preference to cocaine, which does have a local effect? Please omit name.

M.D., California.

ANSWER.—The opium alkaloids as well as cocaine are readily absorbed from the rectal mucosa. Opium produces the desired anodyne effect after absorption. Cocaine is anodyne only as long as it is not absorbed. It may even fail to relieve the pain of hemorrhoids by local action, because the fleeting, superficial anesthesia induced by it does not extend to the nerves of the submucosa that are involved in the inflammatory process.

DIPHTHERIA CARRIERS

To the Editor:—I have a student, aged 8 years, who is a diphtheria carrier. In the treatment of a diphtheria carrier, is diphtheria toxoid or antitoxin of any avail? Or should local treatment be given? Should the student be quarantined? I should appreciate a detailed answer. Please omit name.

M.D., Oklahoma.

ANSWER.—Diphtheria toxoid or diphtheria antitoxin would probably not be of any avail in clearing up a diphtheria carrier. If the tonsils are abnormal they would better be removed; otherwise, ordinary nonirritating gargles may be used. Naturally, the pupil should be kept away so far as possible from other children who may be susceptible to diphtheria, as long as he is a carrier. In chronic carriers, testing the virulence of the organisms is always desirable.

PRESCRIPTION FOR SEBORRHEA OF SCALP

To the Editor:—Please inform me whether the following prescription is an adequate treatment for dandruff:

Zinc sulphate	2%
Salicylic acid	6%
White petrolatum, q. s. ad	100%

Directions: Rub thoroughly into the scalp after a shampoo.

Please omit name.

M.D., Arizona.

ANSWER.—Dandruff is the common name for any scaly condition of the scalp. No single form of treatment can meet all the conditions that cause it, some of which, indeed, are incurable. For an ordinary seborrhea of the scalp the prescription given may be beneficial.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

Alaska: Juneau, March 1. Sec., Dr. Harry C. DeVighne, Juneau.

American Board of Obstetrics and Gynecology: Written examinations will be held in nineteen cities of the United States and Canada, March 26. The general, oral and clinical examination will be held in New Orleans, May 10. Sec., Dr. Paul Titus, 1015 Highland Building, Pittsburgh.

Arizona: Phoenix, April 5-6. Sec., Dr. B. M. Berger, 12 N. Central Ave., Phoenix.

California: *Reciprocity*. Los Angeles and San Francisco, March 16. Sec., Dr. Charles B. Pinkham, 420 State Office Bldg., Sacramento.

Connecticut: *Homeopathic*. New Haven, March 8. Sec., Dr. Edwin C. M. Hall, 82 Grand Avenue, New Haven. *Regular*. Hartford, March 8-9. *Endorsement*. March 22. Sec., Dr. Thomas P. Murdock, 147 W. Main St., Meriden.

Idaho: Boise, April 5. Comm. of Law Enforcement, Hon. Emmitt Pfost, Boise.

Maine: Portland, March 8-9. Sec., Dr. Adam P. Leighton, Jr., 192 State St., Portland.

Massachusetts: Boston, March 8-10. Sec., Dr. Stephen Rushmore, 144 State House, Boston.

Minnesota: *Basic Science*. Minneapolis, April 5-6. Sec., Dr. J. C. McKinley, 126 Millard Hall, University of Minnesota, Minneapolis.

Montana: Helena, April 5. Sec., Dr. S. A. Cooney, Power Block, Helena.

New Hampshire: Concord, March 10-11. Sec., Dr. Charles Duncan, Concord.

Oklahoma: Oklahoma City, March 8-9. Sec., Dr. J. M. Byrum, Shawnee.

Porto Rico: San Juan, March 1. Sec., Dr. A. Ortiz Romeu, Diaz Garcia Clinic, San Juan.

Rhode Island: Providence, April 7-8. Dir., Dr. Lester A. Round, 319 State Office Building, Providence.

West Virginia: Charleston, March 22. Sec., Dr. W. T. Henshaw, Charleston.

New Jersey June Report

Dr. James J. McGuire, secretary, New Jersey State Board of Medical Examiners, reports the written examination held at Trenton, June 16-17, 1931. The examination covered 9 subjects and included 90 questions. An average of 75 per cent was required to pass. Seventy candidates were examined, 67 of whom passed and 3 failed. The following colleges were represented:

College PASSED	Year Grad.	Per Cent
University of Colorado School of Medicine	(1930)	81.2
Yale University School of Medicine	(1930)	82.6
Georgetown University School of Medicine	(1930)	75, 77.1, 77.7, 78.6, 78.7, 78.8, 79.6, 80.4, 81.3, 82.3, 83.3, 83.3, 84.2, 85.2, 86.8
Howard University School of Medicine	(1930)	85.2
Loyola University School of Medicine	(1931)	82.7
University of Maryland School of Medicine and College of Physicians and Surgeons	(1930)	81.5
Harvard University Medical School	(1930)	86.3
Tufts College Medical School	(1929) 86, (1930)	79.8, 89.1
University of Michigan Medical School	(1930)	83.5
St. Louis University School of Medicine	(1930)	75, 78.7, 81.4
Columbia Univ. College of Physicians and Surgeons	(1930)	82.2, 86.3, 87.1
Cornell University Medical College	(1929) 88.7, (1930)	87.4
Long Island College Hospital	(1930)	82.1, 85.7
University of the City of New York Medical Dept.	(1893)	75
Hahnemann Medical Coll. and Hosp. of Philadelphia	(1930)	75.4, 80.4, 80.8, 82.4, 84.3, 85.3, 88.1, 88.8, 89.3, 89.6, 92.5
Jefferson Medical College of Philadelphia	(1930)	79.2, 79.7, 79.8, 80.3, 83.6, 84.1, 84.1
Temple University School of Medicine	(1930)	75
University of Pennsylvania School of Medicine	(1930)	78.6, 79.3, 80.8, 86, 88.7
University of Virginia Department of Medicine	(1930)	79.6, 84.7
University of Toronto Faculty of Med.	(1924) 81.4, (1926)	80.7
McGill University Faculty of Medicine	(1930)	75, 79.5
University of Bologna Faculty of Med. and Surg.	(1926)*	75

College FAILED	Year Grad.	Per Cent
Temple University School of Medicine	(1930)	73
University of Naples Faculty of Medicine and Surgery	(1923)*	64.7
University of Rome Faculty of Medicine and Surgery	(1927)	66

Dr. McGuire also reports 114 physicians licensed by endorsement from Jan. 12 to July 21, 1931. The following colleges were represented:

College LICENSED BY ENDORSEMENT	Year Grad.	Endorsement of
University of Colorado School of Medicine	(1927)	Colorado
George Washington University Medical School	(1930, 2)	New York
Howard University School of Medicine	(1912)	W. Virginia
Atlanta College of Physicians and Surgeons, Georgia	(1912)	Florida
University of Georgia Medical Department	(1927)	Georgia
Jenner Medical College, Chicago	(1915)	Illinois
Rush Medical College	(1925)	New York
University of Illinois College of Medicine	(1930)	Illinois
Indiana University School of Medicine	(1928)	Indiana
State University of Iowa College of Medicine	(1915), (1925)	Iowa
University of Louisville School of Medicine	(1927)	Indiana
Tulane University of Louisiana School of Medicine	(1929)	New York
Atlantic Medical College, Baltimore	(19[illegible]9)	Penna.

University of Virginia Department of Med.	(1930), (1931)	2

Arizona October Reciprocity Report

Dr. B. M. Berger, secretary, Arizona State Board of Medical Examiners, reports 12 physicians licensed by reciprocity with other states at a meeting held at Phoenix, Oct. 5, 1931. The following colleges were represented:

College LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
College of Physicians and Surgeons, Arkansas	(1910)	Arkansas
University of California Medical Department	(1898)	California
Tulane University of Louisiana School of Medicine	(1917)	California
Tufts College Medical School	(1924)	Mass.
Beaumont Hospital Medical College, Missouri	(1900)	Missouri
John A. Creighton Medical College	(1910)	Montana
Columbia Univ. College of Phys. and Surgs.	(1904), (1907)	New York
Starling Medical College, Ohio	(1895)	Ohio
Jefferson Medical College of Philadelphia	(1895)	Penna.
University of Tennessee Medical Department	(1909)	Tennessee
University of Tennessee College of Medicine	(1915)	Tennessee

Book Notices

The Measurement of Man. By J. A. Harris, C. M. Jackson, D. G. Paterson and R. E. Scammon. Cloth. Price, $2.50. Pp. 215, with 87 illustrations. Minneapolis: University of Minnesota Press, 1930.

This excellent volume is divided into four chapters, each written by an authority in his field. In chapter I, on the measurement of man in the mass, the late J. Arthur Harris points out that human attributes are rigidly lawful in their frequency of occurrence and that, when man is studied in the mass, many definite relationships can be detected and quantitatively expressed which would be overlooked if attention were limited solely to the consideration of individuals. The author discusses fully the measurement of type in masses of mankind, the measurement of interrelationship between the characteristics of man in the mass, and the measurement of the relationship between physiologic and physical characteristic in man.

In chapter II, on normal and abnormal human types, Clarence M. Jackson discusses the various racial types of mankind, types of body build, and comparative studies on the height, weight, weight-height index, chest circumference and expansion, vital capacity, pulse rate and blood pressure between male students at the University of Minnesota of purely Scandinavian and German descent. The relationship of the endocrine glands to human body build is briefly summarized.

In chapter III, on personality and physique, Donald G. Paterson reviews the preceding beliefs and knowledge of the subject, takes up the subjects of physiognomy and phrenology, and continues with a discussion of scientific studies of physique in relation to mental traits. He considers height and weight in relation to mental traits, and anatomic age, mental age and body build as related to intelligence and temperament. This is followed by a consideration of physical condition and intelligence. The author concludes by stating that, with the possible exception of physical factors associated with temperamental characteristics and of disease processes involving the higher centers of the central nervous system, no intimate relation exists between bodily traits and mental development. Ordinary physical defects and certain presumably deleterious physical conditions seem to be relatively unrelated to the enormous range of individual differences in intelligence.

In the final monograph, on the measurement of the body in childhood, Richard E. Scammon discusses growth in length, in weight and in surface area of the body in childhood. He then considers the growth of the various parts and organs of the body, and makes an interesting comparison between prenatal and postnatal growth. His conclusions as to the rate of growth are important. He points out that at birth the various organs of the body are growing at a rate of between 5 and 10 per cent of their attained magnitudes. In infancy and early childhood this relatively rapid rate of growth is reduced. The relative growth of the body as a whole (the general type) drops to a minimum at about 7 years of age and later shows a rise to about 12 years of age. The genital organs show little activity in growth until prepuberty, when there is a tremendous rise in their rate of growth, while the nervous system shows no increase in relative rate of growth in later childhood or adolescence. Finally, the lymphoid organs, as the thymus, show not only a relatively decreased rate of growth but an actual negative velocity, an actual loss of weight following puberty.

These monographs should prove of great value not only to the elementary student of this subject but also to all specialists in this field of science.

Theorie und Praxis der Krebskrankheit. Von Privatdozent Dr. Felix Mandl, Assistent der II. Chirurgischen Universitäts-Klinik in Wien. Cloth. Price, 10 marks. Pp. 141, with 28 illustrations. Vienna: Wilhelm Maudrich, 1932.

In the first part of the book the author discusses the incidence of cancer and its social aspects. Some statistics indicate an increase in incidence. An increased predisposition of certain organs to malignant disease is noted. The increased frequency of lung cancer is especially noteworthy. There follows a brief summary of the principal theories of the causation of cancer. Efforts in cancer control in Germany are directed toward the building of diagnostic centers rather than extensive education of the public as undertaken in America. The preventable cancers are enumerated and discussed. The failure to evolve a specific serodiagnostic test for the present leaves the diagnosis of cancer in the realm of microscopic pathology. The general principles of preoperative and postoperative radiation are briefly mentioned. The second part of the book deals with the symptomatology, diagnosis and treatment of the principal forms of cancer affecting various organs. The choice between surgery and radiation is stated in each instance and the value of combining radiotherapeutic and surgical methods is emphasized. The material is well arranged. The presentation is clear. As a concise statement of some of the principal aspects of cancer, this little volume constitutes a practical treatise which will be particularly useful to those having a general interest in the cancer problem.

Diabetes: Its Control by the Individual and the State. By Elliott P. Joslin, M.D. Harvard Health Talks Cloth Price, $1. Pp. 70, with illustrations. Cambridge. Harvard University Press, 1931.

This book is published as one of the Harvard Health Talks, of which some eighteen are now available, an excellent method for education of the public concerning what it should know about disease. The book is written in the usual succinct and, at the same time, attractive style of Dr. Joslin. His analysis of the mortality statistics in diabetes indicates that more people may be dying of the disease but that they are dying at advanced ages. Hence, they are living longer to die of diabetes rather than succumbing to the diseases that used to carry people off in their youth. Dr. Joslin feels that the control of diabetes will demand help by the state in educating the public, endowment of the general practitioner, the establishment of diabetic centers and the proper education of the people in restricted diets that will tend to prevent diabetes. A special section of the book is devoted to the work of the New England Deaconess Hospital, with which Dr. Joslin is associated, and exemplifies the manner in which good results have been accomplished in that institution.

Chirurgische und konservative Kosmetik des Gesichtes. Herausgegeben von Dr. Leander Pohl. Mit einem Geleitwort von Hofrat Professor Dr. A. Eiselsberg. Paper. Price, 25 marks. Pp. 383, with 445 illustrations. Berlin: Urban & Schwarzenberg, 1931.

The object of this book as set forth in the preface is to provide the general practitioner with the necessary information for him to determine whether or not a patient's appearance can be benefited by conservative or surgical procedures. It is also written for the plastic surgeon, giving standard and recent operative procedures without the technical detail usually found in a textbook. The several authors, each writing in his own specialty, belong to the Vienna school, and the treatise is therefore much more coherent than the usual composite work. The first article deals with the normal proportions of the face and is chiefly concerned with anthropometry; it considers the influence of age, race, sex and climate on physiognomy. The second article takes up the changes in the face resulting from internal disorders and is exceedingly interesting for all practitioners of medicine. While the average physician frequently has a clue to diagnosis from the patient's physiognomy, a perusal of this chapter will explain why certain old practitioners frequently make a diagnosis from what is called intuition, whereas their experience and scrutiny of the patient enable them to suspect disease from the facial appearance alone. The effects of faulty circulation, endocrine disturbances, functional disorders, bone disease, nerve lesions, and infections of various kinds are well illustrated. The cosmetic effects of many skin diseases are then taken up, together with a discussion of the most recent treatment of such disfigurations. It is interesting to note that the use of electrocoagulation has supplanted other forms of treatment in many instances of this kind. In the discussion of the subject of plastic operations on the face, many of the former operations which are now obsolete are wisely omitted, and the standard procedures, many of which are based on World War experience, are well described and illustrated. The descriptions of operations on the eyelids and bulb are well delineated and are of value to both the ophthalmologist and the surgeon. Succeeding chapters deal with deformities of the mouth, lips, jaws and palate. These chapters, too, are well written, are concise, and contain essential information. Deformities resulting from malposition of the teeth and their treatment are then taken up. The average surgeon will find here much information concerning the effects of such malpositions on the physiognomy and the value of orthodontia in the young as a method of preventing future facial disfigurement. The final article treats of the making of moulages and prostheses by the aid of "Negocoll" and "Hominit," two new materials which present many advantages over plaster-of-paris models. In conclusion it may be stated that the book fulfils its purpose well, that it will be of great service to the practitioner seeking information on this subject, and that it will also be a valuable adjunct to the library of the plastic surgeon.

Paying Your Sickness Bills. By Michael M. Davis. Cloth. Price, $2.50. Pp. 276, with illustrations. Chicago: University of Chicago Press, 1931.

This volume is published to include studies made under grants from the Rockefeller Foundation. It includes much of the material that Mr. Davis has used in his addresses and his published articles in recent years. He writes well, he has an extensive knowledge of medical conditions and affairs in various parts of the country, and he is able to present the story graphically. Thus he has drawn together a vast amount of statistical and other data concerning medical practice in this country. Through his association with various clinics, dispensaries and other attempts to provide adequate service for the middle class, he is able to contribute first hand information on the costs and the results of such institutions. One of his chapters deals with a study of sickness cost and care in 536 Chicago families based on a report made by the Institute of Medicine. A section on fee tables is enlightening.

Mr. Davis sees the solution of the problem in organized medical service. He calls for medical leadership apparently different from such leadership as is now available, hinting indeed that our present policies are short sighted. Like many other proponents of social medical schemes, Mr. Davis makes his case by shutting his eyes to much of the evidence that the opposition may muster. On page 255, he asserts that the report of the British Medical Association, reviewing the advantages which the British system of health insurance has given to the British medical profession and the public, received no notice whatever in the leading medical periodicals of America and little in less widely read journals. If Mr. Davis had consulted the index to the volumes of The Journal for 1930 he would have found several statements by the London correspondent outlining the plan. If he had cared to inquire at the headquarters of the American Medical Association he would have learned that most serious consideration was given to this report and that knowledge of its background depreciated its value greatly for the informed.

To recapitulate, the information that Mr. Davis has makes anything he writes in the field of medical economics interesting; but the bias, either conscious or unconscious, with which he approaches the subject interferes greatly with any value that it may have for the medical profession.

Archiv und Atlas der normalen und pathologischen Anatomie in typischen Röntgenbildern. Die Harnorgane im Röntgenbild. Von Professor Dr. Eugen Joseph und Dr. S. Perlmann. Fortschritte auf dem Gebiete der Röntgenstrahlen, Ergänzungsband XXXVII. Herausgegeben von Prof. Dr. Grashey. Second edition. Paper. Price, 64 marks. Pp. 87, with 372 illustrations. Leipzig: Georg Thieme, 1931.

The authors have compiled a neat work of reference, presenting all phases of modern urologic technic and roentgenologic diagnostic procedures of the urinary tract. The normal and the pathologic urinary tract are adequately reviewed. These subjects are illustrated with excellent drawings and roentgenograms obtained from the material of their large clinic in Berlin. Numerous case reports are presented with notes in English, German, French and Spanish, giving the clinical observations, the pathologic changes in the roentgenograms and the operative specimen as a confirmation of the preoperative clinical diagnosis. These cases are of particular interest and represent the earnest endeavor of the authors to present a work that will serve as an aid in thorough urologic studies and diagnoses. Anomalies of the kidney, ureter, bladder and urethra are well illustrated with contrast mediums, by either the intravenous or the retrograde route, in the roentgenograms. The sagacity of reporting a case of calcified renal cyst in which operation was not performed may be open to question. Intravenous urography, recognized as a new diagnostic procedure, is given its place in the advancement of urologic diagnostic acumen. Owing to lack of time and experience with the intravenous method, the authors well state that its indications, limitations and usefulness will be more standardized as time goes on. They point out, however, that patients with severe infections (tuberculosis) or bleeding may be examined more readily by the intravenous method. Children, especially boys, and patients with strictures of the urethra or ureter may be spared the incidence of trauma and anesthesia by the use of intravenous urography. They felt that cases of severe trauma to the urinary tract should be ideal cases for intravenous investigation, but because of lack of experience they did not advocate its use strongly. Open operation was favored for severe traumatic cases. The authors briefly outline their retrograde pyelographic technic and plead for the use of small ureteral catheters, recommending a number 5 F. for the average procedure. Small ureteral catheters are followed by less reaction, pain and trauma (colic and bleeding).

Roentgenologic Studies of Egyptian and Peruvian Mummies. By Roy L. Moodie, Paleopathologist to the Wellcome Historical Museum, London. Berthold Laufer, Curator of Anthropology, Editor. Field Museum of Natural History Founded by Marshall Field, 1893. Anthropology, Memoirs, Volume III Paper. Price, $5. Pp. 66, with 76 plates. Chicago: Field Museum of Natural History, 1931.

The science of paleopathology has yielded much information concerning the history of disease as it affects modern man. To this new science Moodie has been a noted contributor. His present contribution, issued in a limited edition by the Field Museum, deals with observations on Peruvian mummies made largely by the roentgenologic method. To the extent that the roentgen ray is limited as an aid in diagnosis, so also are the diagnoses limited, as they concern the mummies. The book contains numerous reproductions of x-ray plates and excellent photographs of bones and of mummy wrappings. It includes not only studies of human beings but also some studies of animals. Of particular interest are the discussions of otosclerosis, mastoiditis and the relics of syphilis as they appear in these ancient bodies.

Pathologie der oberen Luft- und Spoisewege. Abteilung 2. Herausgegeben von Prof. Dr. Felix Blumenfeld und Prof. Dr. Rudolf Jaffé. Paper. Price, 96 marks. Pp. 289-800, with illustrations. Leipzig: Curt Kabitzsch, 1931.

In a review of the first part of this book (The Journal, Nov. 23, 1929, p. 1676), announcement was made that the two parts would not be sold separately; it is now published in a single volume. The five chapters added constitute the major part in both amount and importance: wound healing and regeneration, by Fischer of Frankfort-on-the-Main; inflammations, by Hellmann of Würzburg; the final three chapters, on metaplasia, hypertrophy and hyperplasia, and tumors, by Rudolph Jaffé of Berlin in cooperation with Pfeiffer and Leicher of Frankfort-on-the-Main. The volume is well illustrated; many of the illustrations are in colors; the paper is uniformly heavy. Preceding the subject index at the end is a long index of names of persons mentioned in the numerous bibliographies at the conclusion of chapters, and of even many chapter subdivisions. The work is thoroughly German, the references in these bibliographies comprehensively reflecting German thought and progress in the special fields covered by the authors. Mention of publications in other than the German language is infrequent and then often through the Zentralblätter. The short chapter on hypertrophy and hyperplasia has no illustrations. The remaining seven chapters have, and the first illustration in each is figure 1, which shows how essentially encyclopedic the volume is. The difficulty in such works of maintaining uniformity of pattern, finish and timeliness has been deftly handled. There is little attempt at exhaustive treatment; in fact, the descriptions of disease are brief and vigorous, with ample directions for those who may desire more extensive treatises. As was predicted in the review of the first portion, the complete work has turned out to be a valuable reference work for specialists and for students in general.

The Diagnosis and Treatment of Venereal Diseases in General Practice: The Routine Management of Syphilis and Gonorrhoea Employed in the St. Thomas's Hospital Venereal Diseases Department. By L. W. Harrison, Director of Venereal Department, St. Thomas's Hospital. With a chapter on the Medico-Legal Aspects, etc., by F. G. Crookshank, M.D., F.R.C.P. Fourth edition. Cloth. Price, 25s. Pp. 567, with illustrations. London: Humphrey Milford; New York: Oxford University Press, 1931.

This revised fourth edition is a valuable and practical publication not only for the general practitioner but also for the medical student. It is an excellent book for teaching purposes. A systematic complete examination of all patients is suggested rather than the partial instalment type of observation. The diagnosis of syphilis is taken up with the lesion proved syphilitic, followed by a differential diagnosis of any disorders with which it might be confused. Well chosen illustrations throughout the book give clear-cut typical examples of the lesions usually seen in venereal disease. Treatment of gonorrhea in the male is much the same as followed in the United States. The section on the treatment of gonorrhea in the female has been revised and enlarged. The author devotes some space to a discussion of stricture of the female urethra. Because of its frequency, this is an important phase in the diseases of the lower urinary tract in the female. The use of arsenicals and the heavy metals in the treatment of syphilis is thoroughly discussed. Of the heavy metals, bismuth, because of its higher specific index, is preferred. Syphilitic treatment is outlined by the use of bismuth preparations and neoarsphenamine over a period of years by the interrupted method. A well written concise chapter on public health and medicolegal aspects is presented. The end of the book is devoted to laboratory methods used for the demonstration of micro-organisms, complement fixation and serum reactions.

Hervorragende Tropenärzte in Wort und Bild. Von Univ.-Prof. Dr. med. G. Olpp, Direktor des Deutschen Instituts für ärztliche Mission und des Tropen-Genesungsheims in Tübingen. Paper. Price, 30 marks. Pp. 446, with portraits. Munich: Otto Gmelin, 1932.

This volume contains over three hundred biographies and bibliographies of investigators of tropical disease. The sketches are of about five hundred words each, arranged in alphabetical order. The work thus constitutes one of the most valuable works of reference available on the subject. Full credit seems to have been given to such American investigators as Ashford, Ricketts, Theobald Smith and Flexner.

Pediatric Education. Report of the Subcommittee on Medical Education. Borden S. Veeder, Chairman. White House Conference on Child Health and Protection, Section on Medical Service. Committee on Medical Care for Children. Paper. Pp. 109. New York: Century Company, 1931.

This is a report of the subcommittee on Pediatric Education of the White House Conference on Child Health and Protection. The report is comprehensive and points the way toward the reforms in pediatric education which need to be started. As a result of the study, it is recommended that enlargement of the teaching facilities for pediatrics be made in the medical schools, and that the subject should be taught from the broader aspect. Two hundred hours should be the minimum time assigned to pediatrics in the four year course. The planning of pediatric education along the lines designated in this study will bring about improvement in the instruction in this field.

Diphtherieepidemien der letzten Jahre, das Heilserum und die Schutzimpfung. Von Dr. E. Friedberger, o. Professor der Hygiene, Leiter des Instituts. Paper. Price, 4 marks. Pp. 50, with 56 illustrations. Berlin: Urban & Schwarzenberg, 1931.

The author, professor of hygiene and director of the Institute for Research in Hygiene and Immunology, reports a study of epidemics of diphtheria which he made to determine the value of preventive immunization and the use of antitoxin. In the introduction he cautions against attributing to specific measures of prevention reduction in epidemics which may be due in part to political conditions resulting in better standards of hygiene. Curves are given showing the increase of diphtheria in recent years in European countries, where economic conditions since the World War have presumably adversely affected living conditions as contrasted with progressive lessening in the incidence of diphtheria in the more prosperous countries. There follows a discussion of the various methods for immunization against diphtheria, with numerous illustrations of the propaganda employed by health departments in this and other countries. The author believes that such extensive use of immunization against diphtheria is not justified. He concludes that the preparations used up to now for immunization are ineffective and that on the other hand there is danger of precipitating an attack of the disease in previously healthy carriers of the diphtheria bacillus, a danger that is multiplied if immunization is undertaken at the height of an epidemic. He urges search for a better method of treatment than is afforded by antitoxin. If the author is correct in his assumption that the decrease of diphtheria in America is due not to immunization but to prosperity, recent statistics should show a sharp rise in the incidence of the disease.

Matas Birthday Volume: A Collection of Surgical Essays Written in Honor of Rudolph Matas, New Orleans. Cloth. Price, $10. Pp. 396, with portrait of Dr. Matas and 102 illustrations. New York: Paul B. Hoeber, Inc., 1931.

This volume is a reprint from the *American Journal of Surgery* of a collection of essays in honor of Prof. Rudolph Matas. Most of the essays deal with distinctly surgical subjects discussed by men who have written extensively in surgical fields. A few are historical and outside the field of surgery. The volume includes an appreciation of Professor Matas, a biography and a beautifully printed photograph.

Grosse Ärzte: Eine Geschichte der Heilkunde in Lebensbildern. Von Dr. med. Henry E. Sigerist, Professor an der Universität Leipzig. Cloth. Price, 10 marks. Pp. 310, with 68 illustrations. Munich: J. F. Lehmann, 1932.

Through biography one learns the history of mankind, since history is but a recounting of the acts of individuals and their influences on one another. Professor Sigerist begins his account with the mythical Imhotep and Asklepios, follows with Hippocrates, and then discusses biographically all the great figures of medicine whose names are associated with periods of progress. The style of the book is literary, marked by an excellent vocabulary and by a sense of humor and of the drama. Each of the sketches is illustrated with an excellent portrait. It is fortunate that this book is soon to be made available in an English translation.

Medical Psychology: The Mental Factor in Disease. By William A. White. Nervous and Mental Disease Monograph Series, No. 54. Boards Price, $3. Pp. 141, with 4 illustrations. Washington, D. C: Nervous & Mental Disease Publishing Company, 1931.

Dr. White has in his inimitable way written a brief but pithy discussion of the psychologic factors in disease processes, in which he pleads for a consideration of the patient as a whole individual. His book is not alone concerned with pure psychologic disturbances but the psychology of the physically sick. He discusses the various theories and schools of modern psychologic thought and presents the whole matter in a readable fashion for the nonspecialist. It is a book well worth while in the possession of the internist as well as the psychologist.

Hunger und Appetit: Untersuchungen zur medizinischen Psychologie. Von David Katz. Paper. Price, 4.20 marks. Pp. 70, with 5 illustrations. Leipzig: Johann Ambrosius Barth, 1932.

The author is a psychologist who has done some experimental or observational work on feeding behavior in children and animals. The monograph is of interest mainly to psychologists. Hunger and appetite are frequently confused by the author, and speculations are given undue prominence. Much of the recent objective work on hunger in man and animals is not even referred to. It is not a significant contribution to biology.

Man and Woman in Marriage. By C. B. S. Evans, B.A., M.D. With an introduction by Rudolph Weiser Holmes, M.D., Professor of Obstetrics, Northwestern University Medical School. Cloth. Price, $2. Pp. 113. Chicago: Bruce-Roberts, Inc., 1931.

There seems to be an increasing demand for books to guide young couples in the physical intimacies of married life. Sex education is not a part of the curriculum in any regular institution of education, particularly not the type of sex education involved in sex relations. The book by Evans gives all the advice that anybody needs to know and may be useful to those who do not know it.

Medicolegal

Adjusting Physician's Fee to Patient's Wealth

(Caulk v. Anderson (Texas), 37 S. W. (2d) 1008)

The plaintiff, a physician, attended one Brackenridge. After his patient's death, he brought suit against his executors to recover the reasonable value of the professional services rendered. He pleaded that Brackenridge had been a highly successful business man of advanced age, owning an estate of more than a million dollars; that the services rendered involved his relief from great suffering and the prolongation of his life; and that the performance of such services required the highest professional skill, based on long experience. The trial court permitted the plaintiff to prove Brackenridge's wealth and refused to instruct the jury to disregard that proof. The jury thereafter found a special verdict to the effect that $10,000 was reasonable compensation for the services rendered, and judgment was given in favor of the physician. On appeal by the defendants, however, the court of civil appeals, eighth supreme judicial district, concluded that the admission of evidence as to Brackenridge's wealth, and refusal to instruct the jury to disregard it, constituted reversible error.[1] The plaintiff-physician thereupon appealed to the Supreme Court of Texas.

The difficult and important question for determination, said the Supreme Court, is whether the jury may rightly consider the wealth or poverty of a patient in fixing the reasonable value of the services of his physician. The authorities are divided on the question. The value of a service, said the Supreme Court of Iowa, depends on the difficulty of rendering it, on the skill required in its performance, and sometimes on the results accomplished, but not on the riches or the poverty of the person for whom the service is performed; and, said the court, "There is no more reason why this charge should be enhanced on account of the ability of the defendants to pay, than that the merchant should charge them more for a yard of cloth, or the druggist for filling a prescription, or a laborer for a day's work." *Robinson* v. *Campbell,* 47 Iowa 627.

Such a view, said the Supreme Court of Texas, disregards the essential purpose of the employment of the physician, which is to relieve the pain, restore the health, avert the death, and prolong the life of a human being. Since a cardinal object of the physician's employment is to prolong the life and restore the health of a human being, any evidence bearing on the pecuniary value of such life and health cannot be logically ignored in the search for the truth as to reasonable compensation for the services rendered under the employment. The principle which must govern in this case is the principle that underlies the settled rule in negligence cases, that in ascertaining the pecuniary loss resulting from death or permanent bodily injuries, the jury may consider, not only the age, occupation, habits, and health of the deceased or injured person, but also the amount and value of his property and his earning capacity. Had the patient Brackenridge suffered permanent injury or [illegible] his life as the proximate result of the negligence of his [illegible] in performing his professional duties, no one could [illegible] that he, or a dependent relative, might have proved [illegible] patient's wealth and business capacity, under the established law of Texas, in an action to recover the damages for which his physician would then have been liable. Such testimony would be admissible because it would help to determine the pecuniary value of the patient's health and life. For the same reason, testimony of a patient's wealth is admissible as a circumstance to determine the value of services resulting in the restoration of his health and his capacity to perform his customary duties, as well as in the prolongation of his life.

The services of an attorney in a capital case most nearly correspond to the services of a physician in a capital operation to avert imminent death. In a capital legal case, how could it be reasonably denied that a jury might consider the client's income and estate, in estimating either the pecuniary benefit to accrue to the client from an acquittal, or the responsibility and burden of the attorney? And the Supreme Court of Texas has said that where the burden of an attorney is increased or diminished thereby, the jury may consider the wealth or poverty of the client in determining the reasonableness of the attorney's fees. That doctrine accords with the opinion of Associate Justice Grier of the Supreme Court of the United States in *Lombard* v. *Bayard,* 15 Fed. Cas. 795, No. 8469, 1 Wall. Jr. 196 (affirmed in 9 How. [50 U. S.] 530, 13 L. Ed. 245), where it is said:

> Every gentleman of the bar well knows that there cannot be any one rule of charges in the nature of a horizontal tariff for all cases. Often, where the parties are poor and the matter in contest is small, counsel receive but very inadequate compensation for their exertion of body and mind; and for myself I know that for some of the most severe labor of my professional life I have been the least well paid. In other cases, where the parties are wealthy, and the sum in controversy large, they will receive a tenfold greater compensation for perhaps a tithe of the same labor. In some cases the whole sum in dispute would be poor compensation. In others, five per cent of it will be very liberal. Hence, in all cases, professional compensation is gaged not so much by the amount of the labor, as by the amount in controversy, the ability of the party, and the result of the effort. And this is perfectly just.

That there is in this country a "sliding scale for the costs of the same medical service, which may vary from $25 to $10,000, according to the wealth of the individual," is evidenced by a statement by the Secretary of the Interior of the United States, in reviewing a report of a Committee on Costs of Medical Care. Hence patient and physician must concur in regarding the patient's ability to pay as a matter to be properly taken into consideration in fixing, by express contract, fair medical fees. That which parties quite universally regard as important or even controlling in fixing the value of a certain service by express agreement ought not to be required to be wholly ignored in a conscientious effort to arrive at the reasonable value of the same service when that value has not been agreed upon.

The court of civil appeals erred, said the Supreme Court, in reversing the judgment of the trial court because the plaintiff-physician was permitted to plead and to prove his patient's wealth. For other causes, not pertinent to this abstract, however, the case was remanded to the district court for a new trial in accordance with the opinion of the Supreme Court herein expressed.

Medical Practice Acts: Use of Electric Vibrator and Sun Ray Lamp Not the Practice of Medicine.—A person conducting a gymnasium where baths and massage are given, heat is applied, and an electrical vibrator, together with heat from a sun ray lamp, is used, but no electrical treatments are given, is not practicing medicine without a license in violation of the New Jersey medical practice act.—*State Board of Medical Examiners of New Jersey v. Dussinger (N. J.), 154 Atl. 325.*

Accident Insurance; Aggravation of Preexisting Infirmity.—Though an insured person sustains a personal injury by the happening of an accident, his death is not brought about solely and independently of all other causes by that accident, if it would not have caused his death if he had not been already afflicted with a disease or infirmity.—*Ryan v. Continental Casualty Co. (C. C. A.), 47 Fed. (2d) 472.*

COMING MEETINGS

American Association of Anatomists, New York, March 24-26. Dr. George W. Corner, University of Rochester School of Medicine, Rochester, N. Y., Secretary.

American College of Physicians, San Francisco, April 4-8. Mr. E. R. Loveland, 133 South 36th Street, Philadelphia, Executive Secretary.

Arkansas Medical Society, Little Rock, April 5-7. Dr. William R. Bathurst, 814 Boyle Building, Little Rock, Secretary.

Medical Society of the Missouri Valley, Omaha, Neb., April 5-7. Dr. Joseph D. McCarthy, 107 South 17th Street, Omaha, Secretary.

Mississippi State Medical Association, Jackson, April 12-14. Dr. T. M. Dye, Clarksdale, Secretary.

North Carolina, Medical Society of the State of, Winston-Salem, April 18-20. Dr. L. B. McBrayer, Southern Pines, Secretary.

Pacific Coast Surgical Association, Santa Barbara, Calif., *February 25-27.* Dr. E. L. Gilcreest, 384 Post St., San Francisco, Secretary.

Tennessee State Medical Association, Memphis, April 12-14. Dr. H. H. Shoulders, 706 Church Street, Nashville, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

12: 817-964 (Dec.) 1931

*Value of Hypertonic Glucose Therapy in Preoperative and Postoperative Conditions. J. O. Polak, V. P. Mazzola and L. Zweibel, Brooklyn. —p. 817.

*Pelvic Endometriosis: Spontaneous Rupture of Endometrial Cysts, with Report of Three Cases. E. Novak, Baltimore —p. 826.

Primary Epithelioma of Vagina. L. Mary Moench, Rochester, Minn. —p. 837.

Relationship Between Mother's Gain During Pregnancy and Infant's Birth Weight. P. W. Toombs, Memphis, Tenn.—p. 851.

*Analysis of 100 Cases of Ruptured Ectopic Gestation: Technic and Evaluation of Autohemofusion. J. V. Ricci and S. di Palma, New York.—p. 857.

*Abortion in Relation to Fetal and Maternal Welfare. F. J. Taussig, St. Louis.—p. 868.

Abdominal Operations During Pregnancy: Three Cases. F. C. Hammond, Philadelphia.—p. 878.

*Observations in the Use of Lugol's Solution in Hyperemesis Gravidarum F. H. Falls, Chicago.—p. 882.

Fetal Mortality: Study of 225 Consecutive Fetal Deaths in a Series of 4,668 Deliveries. R. M. Grier, Evanston, Ill.—p. 890.

*Rupture of Corpus Luteum with Intra-Abdominal Hemorrhage: Three Cases. J. P. Greenhill, Chicago.—p. 902.

*Ulcerative Colitis Complicating Pregnancy and the Puerperium. C. S. Barnes and Helen M. Hayes, Philadelphia.—p. 907.

*Clinical Observations on Etiology of Icterus Neonatorum. M. Franklin, Philadelphia.—p. 913.

Endometriosis of Umbilicus: Case. W. M. Thompson, Chicago.—p. 917.

Placenta Succenturiata: Three Cases. E. G. Waters, Jersey City, N. J. —p. 921.

Unusual Case of Pregnancy. R. S. Smylie, San Diego, Calif.—p. 924.

New Demonstration Eyepiece for Teaching Cystoscopy. I. W. Kahn, New York.—p. 926.

Hypertonic Dextrose Therapy.—Polak and his associates believe that shock, dehydration and acidosis are preventable in the majority of cases. In shock the plasma volume and cell volume must be restored. This can be accomplished by prompt treatment, either by direct transfusion or by the intravenous injection of hypertonic solutions of dextrose. The chemical composition of the blood is but temporarily changed when relatively large quantities of concentrated dextrose are used, and the excess passes over into the urine. Intravenous injections of hypertonic solution of dextrose definitely raise blood pressure and pulse pressure and increase the circulating volume of blood.

Pelvic Endometriosis.—Novak reviews the clinical aspects and discusses the etiology and histogenesis of pelvic endometriosis. He reports three cases and cites a fourth from the literature, of spontaneous perforation of unusually large endometrical cysts, with the production of acute abdominal symptoms. In two these suggested acute appendicitis, in the third a presumptive diagnosis had been made of ovarian cyst with twisted pedicle. In the case cited the symptoms had suggested "ectopic pregnancy or acute peritonitis." The author emphasizes that the possibility of this accident should be borne in mind when acute abdominal symptoms develop in cases in which the history and the pelvic observations suggest the probability of pelvic endometriosis.

Ruptured Ectopic Gestation.—Ricci and di Palma suggest the term autohemofusion in lieu of the ill chosen autotransfusion. They have autohemofused eleven patients with ruptured ectopic gestation with sudden profuse or moderately profuse hemorrhage. The procedure is of distinct value for the utilization of the free intra-abdominal blood. The red cells of the intra-abdominal free blood have been found microscopically normal as late as seventy-two hours after the time of the rupture. Autohemofusion is blood economy. Even for patients who are not in imminent danger, i. e., not in urgent need of blood, the salvaging and vascularization of from 300 to 500 cc. of blood (the usual amount found) will help toward an uneventful postoperative reaction and a more rapid recovery. Autohemofusion dispenses with the need of a transfusionist, grouping of serums and group testing, and eliminates the often distressing financial burden. Autohemofusion is a life saving therapeutic measure in the occasional ruptured ectopic pregnancy with a sudden and overwhelming hemorrhage, particularly when such a catastrophe occurs in a small community where the ordinary transfusion is not available within a safe margin of time.

Abortion and Fetal and Maternal Welfare.—Taussig states that an estimate of 700,000 abortions annually in the United States is certainly no exaggeration of the actual condition. There is every reason to believe that an increase in this number is taking place with each decade, similar to the experiences of other civilized countries. This increase is noticed primarily among married women who have three or more children. All efforts to control the incidence of criminal abortion by legislation have resulted in failure. Birth control may prove a factor in the reduction of criminal abortions, especially if more reliable contraceptive measures are discovered. The maternal death loss from abortion in the United States has been estimated as 15,000 annually. Deaths from puerperal sepsis following abortions are relatively seven times as frequent as those from puerperal sepsis after childbirth. The Russian experiment with legalized abortion indicates a definitely lower maternal mortality with operations done openly in hospitals than with secret, illegal operations as formerly. A decrease in maternal mortality can be expected from improving the training of medical students and physicians in the proper management of abortion cases and from an increased knowledge concerning the prevention and treatment of septic infection. The abortion problem, so vital to the human race, demands more careful and more open study, free from the trammels of political or religious dogma. Women should be taught to respect their duties, as mothers, to the social state, and the state in turn should be made to feel its obligations to motherhood, granting such relief, financial and otherwise, especially to those with many children, as will to the greatest degree avoid economic distress and promote the physical well being of the mother. The author believes that the women of this country should be told that interference with pregnancy, even in its earliest stages, is not the harmless procedure they generally seem to consider it but is a procedure inevitably associated with considerable risk to life and especially to future health.

Use of Compound Solution of Iodine in Hyperemesis Gravidarum.—Falls directs attention to the fact that in certain cases of pregnancy with hyperemesis the patients present evidences of hyperthyroidism and are benefited by the treatment for the latter condition. Compound solution of iodine administered orally, intravenously or intramuscularly apparently has been of value both as a prophylactic and as a curative remedy. In his rather small series of patients, some of whom were quite sick when first seen, the author has not had to resort to abortion since he has been using compound solution of iodine.

Rupture of a Corpus Luteum.—According to Greenhill, rupture of a corpus luteum with intra-abdominal hemorrhage, although reported in the literature less than eighty times, is much more frequent than this number indicates. Since there is nothing characteristic in either the history or the physical examination of this condition, a correct preoperative diagnosis can rarely be made. Regardless of this, the condition should be borne in mind when there are evidences of intra-abdominal hemorrhage in women. The chief predisposing factors in the causation of these ruptures are the same as those which are responsible for nonperforative hemorrhages within the ovary; namely, conditions which bring about hyperemia of the ovary and engorgement of its vessels. Trauma not infrequently plays a part. Among the author's three cases, one rupture was produced accidentally during bimanual examination.

Ulcerative Colitis.—The studies of Barnes and Hayes have led them to the conviction that colitis is a more frequent complication of pregnancy than the profession has realized: that the severe form, illustrated by cases presented by them, is probably not uncommon in pregnancy and in grave puerperal conditions, and not rarely the chief decisive factor in fatality. Doubtless the latter was true in their cases. Indeed, one of their patients did not show any pathologic changes that could be ascribed directly to pregnancy or to the puerperium, strongly suggesting that the symptoms of the disease under discussion may so simulate those of a puerperal condition as to lead to a false diagnosis.

Etiology of Icterus Neonatorum.—Franklin believes that, although not one of the theories he enumerates explains the primary cause of icterus neonatorum, some of them do explain secondary causes that are partly responsible for this condition. The theory that the uterine contractions after birth so compress the detached placenta as to force placental and cord blood into the circulation of the new-born and thereby produce the clinical signs and symptoms of icterus neonatorum seems to be the primary cause. The intensity of the icterus seems to depend on the relative proportion between the quantity of blood forced into the circulation of the new-born and the quantity of blood which should normally be possessed by that infant. While the avoidance of delay in tying or clamping the cord will not eliminate icterus neonatorum entirely, it apparently will reduce its incidence materially.

Relation of Tuberculosis to Chronic Uveitis.—According to Finnoff, chronic uveitis is frequently of tuberculous origin. Most cases of tuberculous uveitis are characterized by the formation of nodules. In the diffuse forms, without the presence of nodules, it is difficult or impossible to make a differential diagnosis between the tuberculous and other forms of uveitis from clinical data and symptoms. In these cases, only animal inoculations or microscopic examination of the affected tissue gives positive evidence. All parts of the uveal tract are vulnerable to tuberculous infection. The percentage of cases of chronic uveitis that are due to tuberculosis cannot be accurately estimated from a study of the literature. Tuberculosis is more often the cause of chronic uveitis in persons under 25 years of age than in later life. The symptoms of chronic tuberculous uveitis may be closely simulated by syphilis and sympathetic ophthalmia.

Etiology of Chronic Iritis.—Irons emphasizes the fact that in a comparison of the results of studies of the etiology of iritis, proper interpretation requires a consideration of the relative prevalence of diseases in the populations from which the cases come. Clinical observations and laboratory studies suggest that the mechanism of production of chronic and recurrent iritis includes allergic as well as embolic factors. In a small series of carefully classified cases there is an increasing incidence of evidence of tuberculosis and of probable tuberculous etiology in passing from acute to recurrent to chronic iritis. It is also evident, however, that the presence of evidence of past or present tuberculous infection does not alone warrant the conclusion of a tuberculous etiology.

Pregnancies and Birth Interval Among Indians.—Women living in the pueblos of San Juan and Santa Clara in 1930 were found by Aberle to have between nine and fourteen pregnancies during their reproduction span. The modal interval between births was found to be approximately twenty-four months for Indian women living today, for Indian women living a century ago, for white women of the registration area of the United States in 1921, and for colonial women living a century ago. The birth rate among the Indians of today was approximately the same as that for the population of Copenhagen in the seventeenth century. It is significant that among five widely separated groups of women living under totally different environmental and cultural conditions the reproductive capacity should have been the same. It would seem that fertility was dependent on something intrinsic in the human organism itself rather than on culture or environment.

Relation of Colitis to Polyposis.—According to Bargen, it has been definitely established that colitis is the basis of one form of polyposis. Colitis may bear a relationship to all polyposis of the large intestine, but its relation to the adolescent type would be difficult to establish. Inflammatory disease or irritation of some kind may play a part in the formation of disseminated or solitary polypi. The important differential diagnostic data include a carefully taken anamnesis, general examination, rectal digital examination, observation of the stool and rectal discharges, both grossly and microscopically, sigmoidoscopic investigation and roentgenology. The diseases from which polyposis must be distinguished include tuberculosis of the intestine, chronic ulcerative colitis, diverticulitis and malignant neoplasms.

Respiratory Excursion of Diaphragm.—Thomas demonstrates a technic for recording the amplitude of excursion of the diaphragm on a single film. This is attained by altering the exposure time, voltage or wavelength factors during inspiration. The method is of value as a routine in checking postoperative complications when roentgenoscopy is not available.

The amplitude of cardiac movement during respiration may also be traced.

Treatment of Carcinoma of Skin.—Ericksen and Stenstrom report the results of treatment in 152 cases of carcinoma of the skin treated at the Cancer Institute of the University of Minnesota from 1927 to 1930, inclusive. The epitheliomas are considered under three headings: basal, squamous and basal-squamous, or transitional, cell epitheliomas. Six per cent of lesions diagnosed clinically as basal cell were proved by biopsy to be basal-squamous. Because of this fact and also to determine radiosensitivity, biopsies should be made on all questionable lesions. Basal-squamous cell carcinoma requires a heavier dose than basal cell, and a wider area must be treated. Basal carcinoma practically never metastasizes. If metastasis does occur, the growth probably will prove to be the mixed cell type. Multiple lesions of either type or of both types may occur in the same patient. The main type of treatment used was roentgen therapy with a potential of 100,000 volts and no filter. Radium was used in a few instances. For some lesions, both surgery and radiation were employed, and these cases are discussed separately. The authors emphasize that they did not use any routine treatment but each case was individualized and treated accordingly. Slightly more than 50 per cent of the patients followed were cured (permanently) with one roentgen treatment. It seems probable that a higher percentage of cures from one treatment can be obtained if the initial dose is increased on an average by from 4 to 8 milliampere minutes. One hundred and thirty-three patients are still reporting occasionally for examination and of these, 69 with basal cell, 45 with squamous cell and 5 with basal-squamous carcinoma, or a total of 119 (90 per cent) have remained well from six months to four years. Nineteen patients were lost and fourteen cases were classed as failures. Of the failures, ten were far advanced when first seen. The authors believe that if cutaneous epitheliomas are diagnosed early and receive a proper initial treatment they should practically all be cured by means of roentgen or radium therapy except when cartilage is involved, in which case surgery is clearly indicated.

Deep Burns Caused by Roentgen Rays.—Davis believes that deep burns caused by roentgen rays occur much too frequently and the danger of causing such burns should be stressed rather than minimized. The destructive powers of roentgen rays and radium are very great and must be considered as well as their curative powers. There is no question that, therapeutically at least, these agents should be used only by experts and even then with the utmost caution. Early and wide excision of deep burns caused by roentgen rays or radium, with closure of the defect thus made, by tissue shifting, promises more surely than any other method yet devised the elimination of pain, an excellent prospect of permanent healing and in many instances the restoration of function and, in addition, gives a reasonable assurance of safety from subsequent malignant degeneration.

Absence of Half of Diaphragm.—Jenkinson states that congenital absence of the diaphragm, an uncommon condition, usually occurs on the left side but may be on the right. The condition should not be confused with diaphragmatic hernia or thoracic stomach. Thoracic stomach, a rare condition, does not necessarily shorten life and is comparatively easy to diagnose roentgenoscopically. The roentgenologist should be sure that the stomach, and the stomach only, is located in the thorax. Diaphragmatic hernia should be definitely differentiated from absence of one half of the diaphragm.

Chart Showing Time of Appearance of Centers of Ossification.—Camp and Cilley present a chart devised by them to give roentgenologists the essential data pertaining to the time of appearance of the various centers of ossification and the time of their union. The chart has been a convenient source of reference in the authors' routine work, and frequent requests for copies have prompted them to publish it for the benefit of those interested. Many of the drawings have been copied, with certain modifications, from standard anatomy textbooks and other works of reference pertaining to the subject. The appended information has been compiled from the same sources.

Pneumococcus Type III Pneumonia.—Blake reviews a consecutive series of 122 cases of pneumococcus type III pneumonia admitted to the New Haven Hospital during the ten year period from Jan. 1, 1921, to Jan. 1, 1931. Confirmatory of previous reports, it was found that the incidence is greatest in the later decades of life, approximately 50 per cent of the patients being over 55 years of age. Males were nearly twice as numerous as females. No special racial susceptibility was found. The monthly incidence corresponded to that of pneumonia in general. Acute predisposing causes played an important part in the etiology of the disease, being of undoubted significance in 75 per cent of the cases. The most frequent predisposing causes were the acute respiratory infections—common colds, grip and influenza. These immediately preceded the onset of the pneumonia in 52 per cent of the patients. Exposure, exhaustion and acute alcoholism were recorded in 17 per cent. Chronic disease existed in 66 per cent of the patients and in all probability exerted a significant influence on susceptibility. Chronic pulmonary and vascular diseases and chronic alcoholism were predominant. The onset, the clinical course and the symptomatology of the disease were similar to those of other forms of pneumococcal pneumonia. In young adult life in otherwise healthy individuals the disease ran a mild course with early critical recovery. In the later decades the disease ran a more prolonged course and recovery by crisis was the exception. Pneumococcus complications were of the usual frequency. Empyema occurred six times, pericarditis twice and endocarditis once. Otitis media occurred five times in children. In spite of the high mortality, bacteremia was found in only 18.1 per cent of 116 cases and in only 37 per cent of the fatal cases. In the latter it occurred mostly as a terminal invasion from twenty-four to forty-eight hours before death. In only three cases was a high degree of bacteremia encountered. Although the total mortality in this series was high, 44.3 per cent, it is shown that this was largely determined by the factor of late age incidence and by the prevalence of chronic disease at all ages in those who succumbed. In forty patients not subject to chronic disease and irrespective of age, the mortality was only 15 per cent, while in seventy-nine patients suffering from chronic disease (including two with pregnancy) the mortality was 56.9 per cent. Finally, it may be concluded on the basis of the data presented that pneumococcus type III pneumonia is a highly fatal specific infectious disease due, in general, not to a highly virulent organism that attacks and kills a healthy host but rather to a debilitated, sickly or senescent host that succumbs to what is a relatively mild and uncommon infection in the young and vigorous.

Tularemic Pneumonia.—The case of tularemia that forms the basis of the report by Permar and Maclachlan was remarkable in that there was neither a peripheral ulcerative lesion nor regional lymphadenitis. The principal clinical manifestations were a markedly toxic state and an atypical pneumonia. Tularemia was suggested by the history of handling dead wild rabbits and was confirmed by a positive agglutination test for Bacterium tularense on the patient's blood serum. At necropsy the gross observations in the lung were unusual, indicating an acute lobar pneumonia with much interstitial inflammation and necrosis. The lesion suggested an acute diffuse reaction of granulomatous type. The histopathologic lesion was essentially an interstitial pneumonia, distinguished by multiple miliary necrotic foci throughout the stroma of the diseased lobe. These necrotic foci were identical with those seen in an acute diffuse tularemic infection. An intense and widespread inflammatory edema accompanied the development of the specific tularemic nodules in the lung. The blood vessels of the affected lobe showed great edema of the subendothelial and adventitial connective tissue, with an infiltration of mononuclear leukocytes into these coats. This involvement of the vessels produced much narrowing of their lumens, and complete occlusion by thrombosis was often found. Areas of necrosis of considerable size and irregular outline were a striking feature of the microscopic observations. This necrosis was associated clearly with the vascular lesions just described, and appeared to have been caused directly by the vascular narrowing and occlusion. Thus it may be stated that when a diffuse pulmonary involvement occurs in the course of a tularemic infection, the prognosis must be grave, as acute tularemic inflammation of the lung is a progressively destructive lesion. This is borne out by the data available on fatal tularemia.

Studies in Allergic Migraine.—From the study of 202 consecutive cases, Balyeat and Rinkel conclude that migraine is common in childhood, since in nearly one third of the cases studied the symptoms developed during the first decade. The syndrome is more common in business men, professional men and teachers than in laborers. About 7 per cent of all people in the United States sometime in life suffer from the symptom complex. As in asthma, symptoms of migraine in childhood may vary greatly from those in the adult. Gastric symptoms are usually marked. Migraine is interchangeable in the linkage with other allergic syndromes. A family history of allergic diseases was elicited in 167 out of 202 cases, or 82.1 per cent. Of the 202 cases studied, 81.1 per cent presented other allergic syndromes. From their observations the authors conclude that the exciting factor in all cases of migraine is a specific sensitization. There are many predisposing factors that should be investigated and eliminated. The pathologic change in migraine is probably a local vasomotor dilatation producing a local congestion of the brain corresponding to a hive on the skin. A familial history of allergy or a history of allergic manifestations in one who suffers from headache aids but does not establish a diagnosis of migraine. The treatment of migraine based on allergic observations gives results equal to the treatment of practically any other chronic disease.

Diet in Etiology of Anemia.—Kern believes that anemia from dietary causes results only when an unbalanced diet has been persisted in for a long time. The usual result of such an unbalanced diet is a secondary type of anemia, a chloroanemia. The diet fault in these cases is (1) most commonly a lack of iron and of hemoglobin-building elements, (2) rarely perhaps a lack of one or more vitamins or (3) a combination of 1 and 2. The development of pernicious anemia may perhaps be hastened by diet restrictions (probably of certain animal proteins) in patients with achylia gastrica (partial or complete lack of intrinsic factor for stimulating erythropoiesis). The combination of avitaminosis, low protein and iron intake may possibly at times produce an addisonian blood picture. In rare instances an addisonian blood picture may result from a diet inadequate, through prolonged protein starvation, in the extrinsic factor, which is necessary for the formation of the substance for stimulating erythropoiesis.

Heart and Diaphragm.—Trace emphasizes the fact that the abnormally high diaphragm is not the only source of diaphragmatic dysfunction. The low diaphragm, when pronounced, is productive of a goodly share of chronic invalidism. Its owner is nearly always thin and pale, with a long narrow chest and a protuberant ptotic abdomen. The extremities are cold, and blood and pulse pressures are low. The abdominal organs are palpable. Nearly always the victims of numerous poorly defined digestive complaints, they are not infrequently subjected to many unnecessary and repeated abdominal operations. Frequently, circulatory disturbances assert themselves: dizziness, dyspnea, palpitation and fatigue on exertion bring the patients to the physician. These patients present all the symptoms of an effort syndrome: the heart is small, the pulse weak, and the muscles are flabby. The fluoroscopic examination shows a narrow heart hanging suspended like a drop from the large blood vessels. The diaphragm is low, with poor respiratory mobility, and is definitely separated from the cardiac shadow. The poor filling of the cardiac chambers causes a relative arterial anemia with the subjective sense of exhaustion, and the suspended heart, lacking its diaphragmatic support, is liable to produce such bizarre signs as a paradoxical pulse or even a tracheal tug. A well applied abdominal support quickly brings relief. Prolonged rest in bed and hyperalimentation, aided by insulin, often improve the general condition remarkably. The author believes that the physician, who in physical diagnosis of the lungs takes into consideration the depth and shape of the thorax, the thickness of the parietes, the position of the heart and the mobility of the diaphragm, may profitably be on the alert in evaluating cardiac symptoms also, in connection with two important factors: the position and the mobility of the diaphragm. He will be rewarded by a better understanding of the mechanism of some symptoms and by fewer diagnostic errors, and the patient will profit by more intelligently applied therapeutic procedures.

Malignant Tumors of Lung.—Moses presents a study of eighty-one patients with malignant tumors of the lung. The symptoms presented by these patients varied according to the stage of the disease, the type of tumor, the site of the tumor, the amount of lung tissue involved and the presence or absence of effusion in the pleural cavity. The commonest symptoms were a cough, with or without expectoration, which, if present, was usually bloody at some period of the disease; dyspnea; pain; cyanosis; weakness, and emaciation. Hemoptysis was present in the patients having blood vessels involved in the tumor, with ulceration. Fever may be present in the early stages in the presence of a pneumonitis, which is usually diagnosed as an atypical pneumonia that does not resolve completely; in the later stages, fever is present because of an inflammatory process in and about the tumor. Abstracts of the histories of eleven patients are given, illustrating these conditions. The postmortem observations are reported with nine of these histories. Secondary growths in the lung show an advanced malignant condition in the body and, although electrical treatment may ameliorate the symptoms and prolong the patient's life, not a great amount of benefit is believed to result from the present treatment of these secondary conditions. In primary cancer of the lung, in order to diagnose the condition earlier than is usually done it is necessary that one concentrate one's attention on those patients (1) who complain of a persistent cough without demonstrable causes, (2) who expectorate bloody sputum at intervals, with no tubercle bacilli in the sputum, and (3) who complain of general weakness and loss of weight, and do not react to the usual methods of treatment.

*Lichen Planus Confined to Mouth. H. Fox, New York.—p. 1071.

Yellowing Dermatoses.—Weidman states that a perspective of the pathologic changes, at least in the more obscure cases of yellowing dermatoses, is an additional avenue for arriving at a diagnosis; furthermore, while it sounds platitudinous, it is still in order to repeat that the linkage of the cutaneous pathologic process with analogous or correlated processes of the interior will throw light on the etiology of certain dermatoses. The substances that may occupy the skin and color it are given; the source, nature, kind of tissue affected and relation to clinical entities are discussed. The rather peculiar colloid degeneration met in the skin is compared with the colloid degeneration observed by the general pathologist; it is recommended that cutaneous colloid be considered as that of "colloid milium," that is, essentially gelatinous, and not yellow or positive to the van Gieson stain. In this light it should be added to the list of colloid degenerations already constructed by the general pathologist. The term "adenoma" is employed too loosely in dermatologic language; the criteria for its use are outlined, with application to "adenoma sebaceum." A review of the relevant literature suggests that Brugsch's intradermal test for iron (employing potassium ferricyanide) and carotene as a vitamin are likely to be of service to dermatologists. Observations that the author believes are original are as follows: submammary milia, affinities of carotene for epithelium and fat in frozen sections, the location of fat in xanthosis diabetica, and the demonstration of free fat in the lesions of senile elastosis by means of specific fat stains. Attention is called particularly to the following facts: 1. Fatty degeneration of the hyperplastic elastic tissue in senile elastosis is a frequent (physiologic) accompaniment of cutaneous senescence. 2. Such degeneration is a common complication of scarring processes, perhaps including morphea. 3. Histologic observations per se do not form an adequate basis for a differential diagnosis between pseudoxanthoma elasticum and senile elastosis. 4. Fatty degeneration of the hyperplastic elastic tissue is a hamartomatous phenomenon in pseudoxanthoma elasticum. The similarity in the distribution of senile elastosis to that of rosacea and lupus erythematosus is pointed out; partly on the basis of this similarity a hypothesis is recorded involving an elastic tissue rôle (preelacin in the circulating blood) in the pathogenesis of lupus erythematosus.

Cavernous Hemangiomas.—Light believes that although the majority of patients with angiomas may be successfully treated by means of radium, carbon dioxide snow, high frequency currents or surgical procedures, there are cases in which such methods are not feasible. This is most liable to occur in the cavernous type of angioma. In these cases the injection of irritating chemicals, such as are used in the treatment for varicose veins, may prove successful. The author reports a case of massive hemangioma of the leg which was not suitable for surgical intervention or treatment with physical agents. Remarkable success was obtained by the injection of sclerosing substances. The advantages of the injection method of treatment for hemangiomas are that (1) it may be used when other methods are impracticable; (2) no scarring is produced; (3) it is relatively painless, depending somewhat on the chemical used, and (4) it does not interfere with occupation, as the patient is ambulatory.

Lupus Erythematosus. — According to Cummer, lupus erythematosus can scarcely be regarded as rare in childhood, since general series of cases of the disease show that from 2.3 to 11 per cent occur during or before the fifteenth year of life. Search of the literature showed many cases included in general series as well as the 176 cases that are reported by the author. In a series of collected cases, the ratio of females to males was approximately 7:3. The disease occurs in the Negro as well as in the white child. It may have its onset during the first year of life. The incidence is progressively greater in each five year period of life, there being seven times as many cases in the period from 10 to 15 years, inclusive, as in the first five year period of life. Having started in childhood, the disease may last for many years, a duration of forty-two years having been reported. In general, the course of the disease in childhood, including the appearance of the eruption and its response to gold therapy, does not show any striking difference from that in adult life.

Ringworm Infection.—Schamberg and his associates state that it is obvious that there is a great hiatus between a splendid remedy in the test tube and the effect on a parasite in animal tissues. They have endeavored to produce ringworm in guinea-pigs and in rats, but thus far they have failed, although they have used several strains of fungi. They are now trying out mercury crystal violet and mercury fuchsin in the human subject, for ringworm eczema of the feet. The fungicidal power of these combinations is so strong that they can afford to use a weak concentration, particularly as a strong mercurial might irritate the skin. On the other hand, if one makes it too weak, one lessens the penetrative power of the dyestuff. The authors are therefore tentatively using a 0.25 per cent concentration of the compound in 25 per cent of alcohol, 25 per cent of acetone and 50 per cent of water. With this concentration they have made some attempt to determine its penetration into the horny layer of the skin. After painting a rabbit's ear for three consecutive days, they have removed the area and have made frozen sections of it. Microscopic examination discloses the fact that mercury crystal violet does penetrate the horny layer but does not stain it deeply. Mercury fuchsin is now under trial. Their clinical experience has been too brief to permit of any definitive statements. Their results, however, have been encouraging. In the type characterized by macerated skin between the toes, mercury crystal violet has given good results. Mercury fuchsin has produced encouraging results in ringworm of the nails, which are scraped with glass and painted daily. Mercury fuchsin is cosmetically better adapted for the finger nails, because it is a red dyestuff, whereas mercury crystal violet is a deep violet. In highly inflammatory areas or those to which much roentgen treatment has been applied, the authors prefer first to use other remedies until the inflammation has somewhat subsided. The exact method of application and the exact concentration that will give the best results are still the subject of study.

Antimony Compound for Leprosy.—Kingsbury reports the results he obtained in the treatment of four patients with leprosy by means of 3-3 diamino 4-4 dihydroxy arsenostibino benzene. The preparation is light brown and soluble in water, and it has an acid reaction. It is alkalized by the addition of 9 cc. of normal sodium hydroxide per gram. The resulting disodium salt is diluted with physiologic solution of sodium chloride, so that the final volume is not less than 0.1 Gm. in 10 cc. of solution. This solution is slowly injected intravenously with a small gage needle. The preparation is well borne. In the first case in which this preparation was administered a cure was apparently obtained. In the second and third cases moderate but progressive improvement was noted up to the time the patients were transferred to other institutions. In the fourth case there was an apparent arrest of the disease and a decided improvement in the symptoms and the appearance of the lesions. From his study of the four cases, two of the maculo-anesthetic and two of the nodular type, the author believes that this preparation of antimony is superior to the ethyl esters of chaulmoogra oil, and that the remedy is one that may be of considerable value in the treatment for leprosy.

Pemphigus Neonatorum Congenitus.—Freeman reviews the literature on congenital impetigo neonatorum and reports two cases of the condition. He emphasizes the fact that, unnoticed, congenitally infected infants may be the source of origin of epidemics.

Lichen Planus of Mouth.—Fox gives tabulated statistics on ten cases of lichen planus confined to the mouth, which occurred in four men and six women whose ages averaged 44.6 years. The average duration was four years. The eruption involved the mucosa of the cheeks in every case and the tongue in addition in six cases. Subjective symptoms of a mild type were noted in five cases. Of four patients who smoked, three did so moderately and one to excess. The teeth in general were in good condition. Four of the patients had a history of gastro-intestinal disturbance. None gave a history of syphilis, and in five cases in which the Wassermann test was performed it was negative. Histologic examination confirmed the diagnosis in four cases and probably also in a fifth. The result of treatment was in general unsatisfactory, improvement in some cases apparently being due to arsenicals and mercurials. From his observations the author concludes that lichen planus confined to the mouth is more frequent than is generally supposed, that the clinical differentiation from leukoplakia is usually possible, that the disease may persist for years and that treatment is unsatisfactory.

Tuberculous Enterocolitis.—Goldberg states that tuberculous enterocolitis, as most other forms of tuberculosis, is a lymph-borne disease and as such has a predilection for those portions of the bowel more abundantly supplied with lymphatic tissue. Prophylaxis, as practiced in the prevention of swallowing infected sputum and food, should receive greater attention. The diagnosis of tuberculous enterocolitis in its early stages should call for intestinal roentgenography at the first intimation of a gastro-intestinal upset and such roentgen studies should be repeated on recurrence of symptomatic manifestations when negative observations originally were obtained. The prognosis is not as grave as previously considered, especially in the presence of a pulmonary tuberculosis, which can be controlled. The prognosis is definitely improved by the detection of the intestinal lesion in its inception, and through the use of modern therapy. Treatment should be considered in its newer and wider scope. The properly balanced nonresidue vitamin mineral salt diet should be supplied. Ultraviolet therapy is a most important adjunct. There are definite indications which at times point out the usefulness of surgery.

Radium Therapy in Ophthalmology.—According to Lane, progress in the use of radium in ophthalmology has been slow but steady. Radium treatment is founded on a rational basis. The constant flow of energy from the element and its accuracy of measurement make it of real therapeutic value. The broken dose method has many advantages in ocular therapy. Biomicroscopy is most helpful in following up results of treatment. By its use scattered foci of malignant disease can be located which would otherwise escape detection. The treatment may be long and tedious; frequent follow up work is necessary, but the results fully repay the time and skill required in using radium about the eye.

Lysis of Pneumococcus by Saponin.—According to Klein and Stone, pneumococci are not dissolved by saponin when tested in plain broth culture. Treatment of the bacteria with cholesterol renders them susceptible to complete and rapid lysis by saponin. The cholesterol exerts a direct action on the bacteria, independent of bacterial reproduction. The bacteria must be in contact with the cholesterol for a definite period of time prior to the addition of saponin in order to obtain lysis. Excess of saponin inhibits the sensitization by cholesterol. Conversely, excess of cholesterol inhibits lysis by saponin. Animal fluids, e. g., blood or ascitic and pleural fluids, act similarly to cholesterol. Evidence is presented to show that the activity of these fluids is due to their cholesterol content. When cholesterol is esterified it loses its affinity for saponin and becomes incapable of sensitizing pneumococci to saponin. The authors advance the theory that the lysis is due to a union of saponin with the cholesterol assimilated by the bacteria during sensitization. They call attention to the parallelism between saponin bacteriolysis and saponin hemolysis.

Calcium and Inorganic Phosphate of Serum.—Dupré and Semeonoff state that cabbage fed to rabbits causes a marked rise in the serum calcium and a simultaneous fall in the inorganic phosphorus concentration. Bran and oats fed to rabbits cause a marked rise in the inorganic phosphorus of serum with a simultaneous fall in calcium. A rise in calcium is accompanied by a fall in inorganic phosphorus, and vice versa. There is a definite diurnal variation in the serum calcium and phosphorus levels of the rabbit. The evening calcium level is from 1 to 1.5 mg. per hundred cubic centimeters higher than the morning sample. The change in phosphorus is of about the same magnitude. In view of this diurnal variation, a rise or fall of less than 1.5 mg. per hundred cubic centimeters in serum calcium and phosphorus is of no significance.

Mineral Metabolism in Goiter.—Baumann and his associates studied the relation of mineral metabolism of rabbits to the physiologic state of the thyroid. In thyroid deficiency (caused by feeding rabbits with cabbage until a palpable goiter is produced) there is a retention of calcium, magnesium and phosphorus. The conversion of the thyroid to the normal colloid-containing state by the administration of a small amount of iodine restores the balance of these elements by increasing the amounts excreted. The metabolism of sodium, potassium, chlorine and sulphur is relatively uninfluenced by thyroid deficiency.

Acid-Base Balance.—Lamb and Evvard fed swine for three generations (three and a half years) on a ration of yellow corn, tankage, corn germ meal, and alfalfa meal plus from 200 to 300 cc. of normal sulphuric acid solution daily. No deleterious effects on growth, well being or reproduction were observed in the group receiving the acid. No unfavorable effects on the composition of the bones of representative animals were found. Three generations of rats were produced with no apparent ill effect and with optimal reproduction on a satisfactory grain, casein and acid salts ration which contained a total potential acidity of 15 cc. of normal acid solution per hundred grams of feed. Rabbits tolerated a ration containing a net acidity up to 5 cc. of normal solution daily for each animal, the basal ration being optimal in composition and physical character for rabbits. When the net acid allowance was increased above 5 cc. of normal solution, the rabbits soon succumbed. These animals excreted nearly all the acid as acid phosphates in the urine, having only slight ability to mobilize ammonia for neutralization of the acid.

Calcium Salts of Bone.—Bogert and Hastings made analyses of the untreated outer and inner portions of bone, and of bone cortex treated in the following ways: extracted with alcohol, with ether, with water, hydrolyzed with sodium hydroxide, digested with pancreatin, and ashed at temperatures low enough to avoid loss of carbonates. These preparations were analyzed for their total calcium, inorganic phosphorus, and carbonate content. The inner and outer portions of bone did not differ materially as to inorganic composition. The relative proportions of the inorganic constituents in bone cortex were undisturbed by the different processes to which it was subjected, except that ashing caused a considerable loss of carbonates unless special precautions were taken. Commercial preparations of tertiary calcium phosphate as purchased contain appreciable but variable amounts of carbonate and hence are not uniform in composition. The residual calcium: phosphorus ratio of two samples analyzed was the same but was slightly lower than the theoretical calcium: phosphorus ratio for that salt. In all the bone preparations, the residual calcium: phosphorus ratio approximated that for tertiary calcium phosphate. The calcium phosphate: calcium carbonate ratio varies between 2 and 3, but approximates 2 in all preparations in which the bone substances have been relatively little altered by treatment.

*Studies in Alimentary Canal of Man: IX. Calculation of Gastric Volume. W. A. Sommerfield, Cleveland.—p. 240.

Decompensated Hypertensive Heart.—Lisa presents the microscopic lesions of the heart in a series of ten cases of hypertension with congestive cardiac failure. They consist of miliary necroses with cellular reaction. The histogenesis of the lesions is traced. They apparently have a close relationship to the clinical syndrome and offer a pathologic basis for it.

Relation of Jaundice to Outcome in Lobar Pneumonia.—Elton made serial studies in 224 cases of lobar pneumonia by the daily determination of the icterus index, van den Bergh aqueous (direct) reaction and the quantitative serum bilirubin estimation, and demonstrated that serum icterus manifested in one or all of the three tests is pathognomonic of the disease. The summation of the observations relating to the pneumonic icterus clearly indicates that a therapeutic trial of bilirubin is the logical conclusion of the investigation, particularly since the pigment is believed to be nontoxic when injected intravenously. Although the analysis of the icterus of lobar pneumonia may seem complex because of its relation to the presence or absence of fluid and because of the differences between the white and the black races, the application of these observations to the therapeutic test is simple enough, and may be stated as follows: 1. In the white race one should inject a quantity of bilirubin sufficient to cause the icterus index to pass 16.6 but not to exceed 30, regardless of the presence or the absence of fluid. 2. In Negroes, and when negroid reactions occur in the white race, the icterus index 100 must be attained. By preliminary studies correlating the serum icterus with the physical signs, the addition of surplus bilirubin may be contraindicated in many cases. Additional data on the bilirubin content of pleural fluid, obtained early in the course of the disease, in its relation to the outcome, should be secured.

Studies in Alimentary Canal of Man.—Sommerfield believes that current estimates of gastric volume suffer from defective technic since gastric behavior is influenced by the introduction of unusual foreign substances into the stomach and of unusual conditions into the experiment. To obviate these difficulties of technic a method is presented which requires simply an anteroposterior roentgenogram and a determination both of the obliquity of the stomach and of the distance of the magenblase from the anterior abdominal wall. Simpson's rule, as applied to the volume of a tube of unknown curvature, provides a fairly reliable method of estimating stomach capacity under the particular conditions of the author's small meal experiments. It also provides a ready measure of the changing volume as contents become transferred to the small intestine. The diminishing gastric volume shows rhythmic fluctuations which find their explanation in other studies. Estimated by this method an illustrative 5 ounce (150 cc.) buttermilk meal in a healthy young adult stomach bespoke an average volume of only 643 cc. when measured over the first thirteen minutes after swallowing. Since this is greater than the amount swallowed, the secretion of gastric juice must account for the difference.

*Primary Carcinoma of Lung: Bronchiogenic Cancer: Clinical and Pathologic Study. B. M. Fried, Boston.—p. 373.

Primary Carcinoma of Lung.—From the material studied by Fried it is apparent that a reasonable classification of bronchiogenic cancer based on clinical features is as superfluous at the present time as that based on their gross anatomic structure. Indeed, even the "typical cases" in the author's arbitrary classification display such an amazing diversity that one rarely can find a group of patients with similar symptomatology. Nevertheless the "typical" category of bronchiogenic cancer does not represent as a rule any unusual diagnostic difficulties, provided of course one keeps in mind the fact that the disease is far from being uncommon. The symptomatology is briefly recapitulated thus: The onset of the disease, which manifests itself in most instances in persons between the ages of 50 and 70, is as a rule insidious. A grunt or a cough productive of a mucoid or a mucopurulent sputum intimately mixed or only streaked with blood is one of the first complaints. Not infrequently there occurs also a small hemoptysis. A sharp stabbing pain in the chest is a characteristic sign noted by all observers and is looked on as a cardinal symptom which other diseases rarely give. Loss of weight, appetite and strength, pleural effusion, dyspnea and cyanosis occur in all likelihood in the more advanced stages of the disease. Many patients show an asymmetry of the thorax with the narrowing of the affected side; in a high percentage of them there are clubbed fingers and sometimes a diffuse osteo-arthropathy. Many of the author's patients also showed a kyphosis. The physical signs found in the chests of these patients are rather scant and not characteristic. This holds equally true for most chronic pathologic conditions of the lungs. The interpretation of the signs is evidently based on the same laws as that of other intrathoracic diseases. The difficulty in making promptly a correct diagnosis is due to the similarities existing between this disease and a number of other chronic pulmonary diseases. In fact there is not a single "irrefutable" symptom or a group of symptoms which is not common to tuberculosis, to an abscess of the lungs and to a bronchiogenic cancer. Indeed, most observations are to the effect that the last condition is usually confounded with phthisis or with a pulmonary abscess. In certain instances it may be mistaken for an aneurysm of the aorta, and in two of the author's cases it was interpreted as a pulmonary infarct. In the differential diagnosis one must also consider Hodgkin's disease (seen usually in younger individuals), forming a rounded mass confined to the mediastinum or as diffuse pulmonary lymphogranulomatosis, a thymoma, and a teratoma of the lung. In a few cases echinococcus cyst and actinomycosis of the lung have been observed giving symptoms and signs analogous to those found in primary carcinoma of the bronchus. Unlike the "typical" cases, the diagnosis of an atypical case is met by insurmountable difficulties. Of particular interest are those cancers that have shown early metastases to the central nervous system, in which instance the metastatic cerebral lesion simulated a rapidly growing glioma, causing such acute intracranial symptoms as to make an intracranial operation an emergency procedure.

*Abortive Poliomyelitis: Two Cases. J. H. Musser and L. A. Monte, New Orleans.—p. 475.

Treatment of Aortic Aneurysm by Jugulocarotid Anastomosis.—Matas sees little to commend, either in theory or in practice, in the treatment of aortic aneurysm by jugulocarotid anastomosis. Medicine and surgery can still do much for these unfortunate patients, but the greatest hope for their redemption lies in the prophylaxis and treatment of the disease—syphilis (syphilitic aortitis), which is chiefly responsible for the existence of aortic aneurysms.

Abortive Poliomyelitis.—Musser and Monte emphasize the importance of recognizing poliomyelitis from the point of view of the epidemiology of the disease. The mild, abortive and unrecognized cases presumably are responsible for the spread of poliomyelitis. In questionable instances lumbar puncture should be performed promptly and even repeatedly, in order to make a diagnosis, which, while not made with the definiteness of such a condition as meningitis, in which the organisms are identified, nevertheless is substantially trustworthy in the majority of instances.

Tumors Complicating Pregnancy and Labor.—In a study of the case records of 2,150 pregnant women, Mathieu and Holman noted 131 tumors of the pelvic organs in 115 women. There were 10 miscellaneous tumors, 15 cervical polypi, 21 ovarian cysts, 20 vaginal cysts and 65 uterine fibroids. They believe that while the pregnant patient with uterine fibroids must be individualized, the tendency should be away from operation, because dystocia is not apt to occur, especially if the tumor is not in the pelvis. While the incidence of abortion, miscarriage, premature separation of the placenta, hemorrhage and uterine inertia is increased, too often operation will not accomplish the desired result. The very fibroid that will cause dystocia because of its position and impaction in the pelvis cannot be removed by myomectomy without disrupting either the pregnancy or the uterine integrity. For this reason the conservative treatment and the display of the best obstetric judgment in caring for patients with fibroids impacted in the pelvis or with multiple fibroids of the uterus preventing dilatation of the cervix lies in performing elective cesarean section at term.

Varicose Veins.—According to Dixon, there are various sclerosing solutions that may be used in the treatment of varicose veins. Embolic phenomena, although not entirely absent following this type of treatment, are extremely rare and much less common than following surgical procedures. There are certain contraindications to injection of varicose veins, of which hypertension, marked arteriosclerosis, and existing or recent phlebitis are important. In cases of pregnancy, treatment of existing varicosities should be administered at least with caution. The elastic adhesive bandage has been of great aid to healing of these ulcers of the lower extremities, which are secondary to varicose veins. The sclerosing method of treatment of varicose veins and kindred ulcers is not only effectual but, because the patient may be ambulatory, is of economic importance.

Postoperative Use of Therapeutic Pools.—Lowman states that underwater exercise promotes earlier return of function in operative bone and joint work than can be obtained by almost any other modality. The physiologic use of the parts affected and the rest of the body improves metabolism and hastens the healing process. Movement without spasm and joint friction is possible through a large arc. Motion and weight bearing can be accurately scaled to dosage, either separately or together. The morale in long-drawn chronic cases is greatly heightened; the hospitalization time is shortened, and economy results.

Notes on Dengue.—According to Holt and Kintner, there is certainly an immunity to dengue fourteen days after an attack, both to the original infecting medium and to the virus of two outside cases. Peculiarities in the behavior of attacks of dengue, two cases of which are reported, coupled with the fact that immunity to the homologous strain has been proved numbers of times, lead the authors to believe in the existence of "strains" of dengue virus. The virus of dengue was transferred from mosquito to mosquito by feeding for three transfers but was lost before the fifth transfer. There was no discoverable attenuation of the virus as a result of the three transfers. Freezing dengue serum at —7 F. for forty-eight hours did not destroy the virus, nor was it attenuated. Concentrated "immune bodies" from the serum of recovered cases of dengue do not affect the course of the disease when injected on the first day of the attack.

Peptic Ulcer.—Fogelson describes experiments in which he noted that gastric mucin prepared from hog's stomach is only a mild excitant of gastric secretion. It has a high combining power. Two ounces (60 Gm.) of mucin placed in the stomach of the dog was more than sufficient to combine with the acid secreted in response to the injection of 1 mg. of histamine. When half an ounce (15 Gm.) of mucin was mixed with a pound of meat and fed to a dog, free acid did not appear in the dog's stomach throughout the period of observation of from five to seven hours. Complete relief from symptoms for varying periods of from three to twenty months and complete restoration to economic fitness were afforded to sixty-six out of sixty-eight patients with classic ulcer histories and roentgen signs of peptic ulcer by feeding them about 100 Gm. of powdered neutral gastric mucin obtained from hog gastric mucosa. As a rule, half an ounce was given at 10 a. m., and at 2, 4, 8 and 10 p. m., and in addition, from 15 to 30 grains (1 to 2 Gm.) of mucin in capsules on the hours when the large doses were not given.

Blood Picture of Normal Laboratory Animals. R. A. Scarborough, San Francisco.—p. 199.

Changes in Fluids Within Peritoneal Cavity.—Schechter describes experiments in which he demonstrated that the electrolyte composition of isotonic solutions of sodium chloride, of sodium chloride-sodium bicarbonate, and of dextrose, injected into the peritoneal cavity, tends to approach the composition of edema fluid. Isotonic sodium chloride and sodium chloride-sodium bicarbonate solutions tend to be absorbed from the peritoneal cavity at a constant rate, which is almost identical for the two solutions. During the process in which the composition of the dextrose solution is being altered, the volume in the peritoneal cavity markedly increases. After the dextrose concentration has fallen considerably, absorption proceeds at approximately a constant rate. The profound changes occurring in dextrose solution suggest that it is this marked initial lack of equilibrium between this solution and blood plasma that is the underlying factor for some of the phenomena of irritation observed in its subcutaneous or intraperitoneal use.

Acute Disseminated Lupus Erythematosus.—According to Weidman and Gilman, the dermatologic changes known as acute disseminated lupus erythematosus can occur in connection with acute infectious processes and, reasonably, quite apart from tuberculous factors. This does not mean that the tubercle bacillus is incapable of provoking the same cutaneous expressions; the way is still open to demonstrate this possibility. The authors consider it regrettable that the term "lupus" was ever linked with this condition, since it connotes, particularly to the general practitioner, a tuberculous etiology. They belong in that group of dermatologists which believes that acute disseminated lupus erythematosus pathologically speaking is, in many cases at least, of the order of a chronic erythema multiforme. They thoroughly understand that this does not militate against the value which the condition has as a clinical entity (1) in relation to prognosis and (2) in being so comprehensive a process as to admit tuberculosis into the etiology. Incidentally, this concept calls up for reexamination those cases of chronic discoid lupus erythematosus which precede the acute ones, and would assign to them also a possible nontuberculous as well as tuberculous causation, provided one can be sure that the acute and chronic phases have a common causation. However, with tuberculosis so commonly complicated by acute bacterial, even suppurative states, a chronic lupus erythematosus of tuberculous causation could still be reconciled with a superimposed acute condition that was of nontuberculous causation.

Retinal Gliomas Treated by Radon Seeds.—Moore and his associates demonstrated that a radon seed of at least 5.3 millicuries may be inserted into the eye, and that at least five seeds, each of a strength of 3.5 millicuries, may be applied to the outside of the sclera without causing sloughing of any of the tissues. It was found that the technic of insertion and subsequent removal of the seeds did not present any difficulties. It is shown that a retinal glioma will disappear under the influence of radon seeds and that in a concrete case a glioma of moderate size not only was not increased in size twenty-two months after the commencement of treatment but was shrunken and seemed to be completely scarred.

Secondary Hemorrhage After Prostatectomy.—Fullerton describes a hemostatic rubber bag that differs from the Pilcher bag in being spherical instead of pear shaped. One objection to Pilcher's bag is that it enters the membranous urethra and stretches the compressor urethrae muscle, causing temporary or permanent incontinence. The improved bag, being spherical, can be made to fit accurately into the prostatic cavity and cannot enter the membranous urethra. A catheter is first passed into the bladder—a soft rubber by preference—but if this does not enter easily a gum elastic may be used. Through the suprapubic wound light forceps, such as Desjardin's gallstone forceps, are then introduced and the catheter gently felt for. As a rule the latter can be easily seized by the forceps and brought out of the wound. It may be necessary to introduce the finger to locate the catheter, but this should be avoided if possible, as it causes a good deal of pain. The urethral tube of the hemostatic bag is then pushed over the end of the catheter and secured by tying round both a piece of linen thread or any available substitute. The tube and bag are then smeared thickly with melted sterile petrolatum to facilitate withdrawal of the urethral tube and to prevent the bag from becoming unduly embedded. The catheter is then withdrawn through the urethra, bringing the bag, which is thin and collapsible, into position. The bag is then distended by filling it with water. When distended it bulges over the edges of the prostatic cavity and makes contact with the walls of the latter, so that pressure can be exerted on both by light traction at the urethral end. This pressure is kept up by attaching a weight to the tube emerging from the urethra by a piece of cord, which can be brought over the foot of the bed. The bag must not be overdistended, otherwise it will not fit snugly into the prostatic cavity but press on the base of the bladder, and may even, if large, exert injurious pressure on the ureteric orifices. The bag is kept in position for two or three days but is not finally removed until it is judged that all risk of hemorrhage has ceased. It may be allowed to collapse and remain in the bladder as a precautionary measure. Meanwhile, the urethra is irrigated by the side of the tube now acting as a tied-in catheter, silver nitrate, potassium permanganate or other suitable solution being used. This minimizes the risk of urethritis from the presence of a foreign body. This precaution the author always adopts when using the indwelling catheter. When it has accomplished its purpose, the bag may be removed easily through the suprapubic wound. To prevent infecting the bladder by drawing the exposed part of the urethral tube, which may be contaminated, back through the urethra, the bag may be cut off close to the meatus before removal.

Puerperal Fever.—Paine studied two cases of puerperal pyrexia with a view to determining the source of infection. Bacteriologic examination of the secretions of the patients and the throats of possible carriers was made and several strains of hemolytic streptococci were recovered. Possible sources of infection are discussed, and evidence of the source of infection by means of agglutinin-absorption tests is deduced. In both cases it was shown that the infecting organism was carried in the throat of a midwife who attended both patients.

*Buffer Substances of Gastric Juice, and Their Relation to Gastric Mucus. T. C. Mitchell.—p. 427.

Gastric Function and Blood Composition.—Apperly and Crabtree describe experiments which indicate clearly (1) that gastric acidity varies with the fasting plasma bicarbonate, irrespective of how this is produced, or whether there is an acidemia or an alkalemia, and (2) that emptying time varies with the hydrogen ion concentration of the blood. The amount of acid secreted by the stomach mucosa is determined by the carbon dioxide dissolved in the plasma.

Diathermy and Blood Volume.—McIntosh noted that the passage of a high-frequency alternating current of from 200 to 350 milliamperes through a rabbit for about an hour caused a reduction of the amount of blood and plasma in active circulation. This result is independent of the heating effect of the current exerted on the body as a whole.

Urea Excretion.—Dunn and his associates determined the renal extraction ratio for urea by experiments on normal rabbits that had not received additional urea. They found that it lies between 6 and 13 per cent. In the experiments, the amounts of urea extracted per minute from the blood by the kidneys were in satisfactory agreement with the amounts of urea excreted per minute by the animals previously. The renal circulation rates found lay within the normal range, of the unanesthetized animal as determined by experiments with dyes. The renal extraction ratios found in these experiments may therefore be taken to represent the normal range for the unanesthetized rabbit.

Buffers in Gastric Juice.—Mitchell states that the buffer substances present in acid samples of gastric juice are proteins and their derivatives; in anacid samples, carbonates are present in addition. The buffers of the gastric juice are almost entirely dialyzable. The undialyzable protein has only a slight buffering power. Its digestion by pepsin does not materially increase the buffer. The buffering power of the "protein series," i. e., complete proteins, albumoses, peptones, polypeptides and amino-acids, is proportional to the numbers of amino and carboxyl groups available for combination with acid and alkali; these are relatively most numerous in the amino-acids. The buffers present in the form of polypeptides and amino-acids appear to be secreted as such.

*Malnutrition Factor in Rheumatoid Arthritis. F. D. Howitt and W. F. Christie.—p. 1282.
*An Epidemic of Bulbar Type of Poliomyelitis. W. G. S. Brown.—p. 1287.

Malnutrition Factor in Rheumatoid Arthritis.—Howitt and Christie give the case histories of twenty persons with rheumatoid arthritis whom they placed on a six weeks' course of insulin and dietetic treatment while receiving physical therapy. All the patients declared that their general health had improved. Appetite was increased, and in some cases an actual aversion to food was overcome. Naturally, those who ate heartily felt better, but in every case there was also a gain in weight, amounting from 4 to 10 pounds (1.8 to 4.5 Kg.). That this general physical improvement was not due solely to increased food consumption was shown by the amelioration of those other symptoms which accompany sympathetic overstimulation. In particular, fatigue was not produced so quickly or so easily. All the patients except one felt that their joints were freer in movement and not so painful. In some, the less affected joints cleared up altogether; in others, the swelling diminished. Roentgen examination of the hands has not so far revealed any return of calcium salts or other change as a result of treatment, but if the condition of osteoporosis appeared to be no better, at any rate it was stationary and not worse.

Bulbar Type of Poliomyelitis.—Brown reports an epidemic of poliomyelitis in which all the cases were of either the bulbar or the abortive type. There was no spinal case in the epidemic. The clinical features of the prodromal or abortive cases were not such that a sporadic case could be diagnosed. The most typical features were vomiting or nausea at the commencement of a feverish attack with a slight cough. Pharyngitis was present in every case; the child did not feel particularly ill and appeared to have recovered by the third day. Bulbar involvement developed on the third or fourth day of the prodromal period. There was an increased cough and the child now looked ill and perhaps frightened. A cranial nerve palsy developed on the third to ninth day of the illness, though most usually on the fourth or fifth day. The diagnosis was confirmed experimentally in monkeys by the neutralization test. Control tests were made with physiologic solution of sodium chloride and serum. As a result of the experimental work, immunity was shown to have developed in the abortive cases and in several contacts. Evidence in favor of a spread from case to case is produced. The incubation period is shown to be from seven to nine days in the cases in which a contact infection can be assumed.

*Some Thoughts on Term Acute Disseminated Encephalomyelitis and Its Affinities. O. Latham.—p. 677.
*Goiter Prophylaxis. K. D. Fairley.—p. 681.

Acute Disseminated Encephalomyelitis. — According to Latham, it would seem that the striking syndrome of many islets of demyelination in the spinal cord and brain as seen in postvaccinal encephalomyelitis reveals not a disease of specific entity but a form of lesion that can occur (even if rarely) during the course of innumerable other diseases, mostly infections. Further, whether the causal agent is the germ of the particular exanthem involved or a special virus which creeps in or is inactivated for evil during that exanthem, the rôle of impaired vascular function must not be overlooked. Finally, the pathology of acute disseminated encephalomyelitis includes phenomena common to many other diseases, and even states induced by chemical means in the central nervous systems of animals.

Goiter Prophylaxis.—Fairley emphasizes the fact that, of all known diseases, simple goiter is the easiest and cheapest to prevent. Its prevention would have beneficial effects on many related disorders. Iodized table salt of a strength of 1 part of potassium iodine in 250,000 parts of salt is an effective and safe prophylactic for general use. If prophylaxis is limited to the school population, the ingestion of 5 mg. of iodine every week is effective and has no harmful effects. The use of prophylactic measures during pregnancy is of the utmost importance. The individual practitioner can play a most effective part in the prophylaxis of goiter.

Familial Hepatic Infantilism.—Exchaquet discusses the case histories of three children belonging to the same family, one aged 12½ years and two aged 4½ years, the latter being twins. The principal anomalies are large abdomen, hepatomegaly and subnormal physical development. Retardation of development is estimated at from one and a half to three years. In the absence of rickets or of any apparent disturbance of the endocrine system, this retardation is undoubtedly due to the condition of the liver. The author gives the three existing theories seeking to explain the relation between hepatic disturbances and infantilism and offers a modification of the third more adapted to his cases. Each child has hypoglycemia and a corresponding increase of lipoids and cholesterol in the blood, and this hypoglycemia seems to explain the retarded development through lack of carbohydrates. The liver is increased in size by an abnormal accumulation of glycogen because the production of amylase is inadequate. The condition of the children has improved on a more appropriate diet; 50 Gm. of raw liver given daily may have had some beneficial effect; epinephrine by mouth or injection gave inconclusive results.

Pure Pulmonary Amebiasis: Emetine Therapy. Dargein and Plazy.— p. 1639.

Roentgenoscopy in Adenopathy of Hilus of Lung and Cancer of Thymus.—Caussade reports his observations on a woman, aged 25, with a primary cancer of the thymus which appeared in the roentgenogram as a large, deep-seated spherical, dextrolateral opacity occupying the anterosuperior part of the thorax. Ordinarily this condition appears in patients past 50. The tumor was latent a long time and was not revealed until four and one-half months before death. The clinical picture was characterized at first by dysphagia and afterward by an esophageal (cancerous) stenosis. The tumor is purely destructive in contrast to simple hyperplasia (hypertrophy of thymus and goiter); the result is compression and deviation or forcing back of the organs. The latter can help differentiate the malignant processes from the benign processes. The author calls attention to the possibility of infection of mediastinal tumors (primary or secondary) by organs (in his case the esophagus) normally septic. In regard to whether one can recognize by roentgenography a cancer of the thymus when the tumor is situated laterally and whether extirpation can be performed, the author asserts that in the first case one deals only with presumptions, and in the second case the intervention is possible and the tumor can be enucleated only when the operation is performed early. However, toleration and the prolonged latency of the neoplasm permit it to develop to a considerable degree and to invade and cancerize the esophagus before the appearance of clinical signs.

Oily Suspension of Insulin for Therapy.—Rathery and his co-workers assert that their therapeutic results with insulin suspended in oil have been indefinite and extremely inconstant. Insulin in oil is absorbed but often not completely, and the quantity absorbed varies for the individual and in the same individual at different times. This method of medication often fails and is sometimes dangerous, especially when absorption is abrupt and massive. The danger of abrupt and massive absorption prevented the authors from continuing their researches and using larger doses at less frequent intervals. The authors believe their results contraindicate the use of insulin in oil; they do not believe that the oily suspension of insulin can replace the aqueous suspension.

Perforations of Gastroduodenal Ulcers into Free Peritoneal Cavity: Twenty-Five Cases. R. Chabrut.—p. 658.

Hyperparathyroidism in Osseous Dystrophies and in Ankylosing Polyarthritis.—Welti states that hypocalcemia is due to hypoparathyroidism as hypercalcemia is due to hyperparathyroidism. But although functional disturbances of the parathyroids modify the calcium content of the serum, it does not follow that hypocalcemia increases the calcium content of the bony tissues: osteomalacia may coexist with tetany. Hypercalcemia is experimentally produced at the expense of the bones and raises the question of whether certain osseous dystrophies with loss of calcium in man are not caused by hyperparathyroidism, which would justify parathyroidectomy. Many reports state that hypertrophy of the parathyroids is the rule in osteitis cystica fibrosa, and anatomic, clinical and therapeutic facts given by the author tend to prove that this hypertrophy is the cause of the disease, although certain reserves have to be imposed because the results are not uniform or complete with parathyroidectomy and most of the patients have not been followed long enough to allow of a definite conclusion. In rickets the rôle of the parathyroids is secondary only. In osteomalacia coexistant with tetany, the cause is hypoparathyroidism. Osteitis deformans can be ruled out. In ankylosing polyarthritis, relief by parathyroidectomy is doubtful and justified only in the presence of hyperparathyroidism. The author concludes (1) that parathyroidectomy is useful in osteitis cystica fibrosa and in selected cases of ankylosing polyarthritis, and that a preliminary biopsy is advisable in the first mentioned disease even when the diagnosis appears evident; (2) that parathyroidectomy should be proposed as the logical treatment of disorders of the bones and the joints secondary to hyperparathyroidism, which is diagnosed by reduced muscular tonus, reduced electrical irritability of nerves and muscles, presence of generalized pains in the bones, elevation of the calcium content of the blood, and excessive elimination of calcium in the urine. Two methods of quantitative analysis of the calcium content of the blood serum are appended.

*Pathogenesis and Surgical Treatment of Angina Pectoris. P. Mauriac and P. Broustet.—p. 401.
Acute Ataxia of Malarial Origin. G. Sykiotis.—p. 409.

Pathogenesis and Surgical Treatment of Angina Pectoris.—Mauriac and Broustet discuss angina pectoris with regard to the syndrome caused by irritation of the extracardiac plexus, the aortic syndrome, the intramyocardiac syndrome, the pressure reflexes, the anatomy of the heart and the principles underlying surgical intervention. They assert that surgical intervention gives encouraging results. The operative risk does not exceed 10 per cent. Sixty per cent of the patients show improvement ranging from appreciable diminution of the crises to their complete disappearance. In 30 per cent of the cases the results are fair. However, even in the fortunate cases one cannot hope to bring the heart back to its full activity; the lesions of sclerosis, myocarditis and aortitis still remain. But the suppression of pain and the crisis itself with all its dangers is an accomplishment. Bedridden patients have been rendered active. Some surgeons report the results lasting five or six years. But no one designates the number of these successes or failures. The various workers do not define sufficiently what they consider are successful surgical interventions, the actual functional state of the heart, the physical capacity of the patient after recovery or the operative mortality. The authors advise that physicians determine, by all clinical and physical means at their disposal, the state of the myocardium before prescribing surgical intervention.

*Tuberculous, Hydropigenous Nephritis and Lipoid Nephrosis. L. Bernard and J. Paraf.—p. 1589.
Eczemas: Tegumentary Dystrophies in Venous Diseases. G. Delater. —p. 1591.

Tuberculous, Hydropigenous Nephritis and Lipoid Nephrosis.—Bernard and Paraf do not believe that lipoid nephrosis is a distinct nosologic entity. Anatomically, the degenerative epithelial lesions, with fatty infiltration of the tubules, and the inflammatory lesions of the glomeruli and the connective tissue are similar to nephritis; clinically, nephrosis is characterized by edema, massive albuminuria and an absence of chloride and nitrogen retention. The humoral syndrome, which according to German workers distinguishes lipoid nephrosis, includes the presence of double-refractory bodies in the urine and especially hyperlipoidemia with diminution of proteins and inversion of the serum-globulin relationship. However, the morbid picture is not always so regular. There are great variations in symptoms, evolution, course and complications of the disease that do not help to individualize it. The authors assert that syphilis and pneumococcus infections have been found as part of the syndrome, and frequently the same anatomoclinical symptoms are met in tuberculous patients; whereas the humoral syndrome characteristic of nephrosis is found more or less completely in hydropigenous nephritis associated with tuberculosis, and the same nephropathies are demonstrated at necropsy. The authors describe three personal observations in detail. Their studies prove that hydropigenous nephritis, with or without lesions showing amyloid degeneration, is often traced to tuberculosis. Hydropigenous nephritis occurs, on the one hand, in confirmed tuberculous patients; on the other hand, it occurs as a primary disturbance without recognizable cause—it is not until a later time that biologic reactions, clinical manifestations or examinations at necropsy prove the tuberculous origin. The prognosis and treatment should not be modified because of the presence of a lipoid humoral syndrome. The prognosis should be dominated by the gravity of the tuberculous infection and the intensity and nature of the renal impermeability.

Pneumothorax Therapy in Nontuberculous Pulmonary Diseases.—Popowski and Stankiewicz observed 130 cases of nontuberculous bronchopneumonia during a period of two years. They review ten of these cases (three instances of deep-seated pulmonary gangrene, six of bronchopneumonia, one of bronchiectasis) in which artificial pneumothorax therapy was used and draw the following conclusions: Artificial pneumothorax is an auxiliary method in the treatment of bronchopneumonia. It should not be used in any but exceptional cases: the indications and contraindications should first be determined. Pneumothorax therapy is indicated in deep pulmonary gangrene, unilateral bronchopneumonia complicated or uncomplicated by interlobar exudate, unilateral bronchopneumonia accompanied by dyspnea and cyanosis, slow chronic bronchopneumonia with tendency to bronchial dilatation, and beginning bronchiectasis. Pneumothorax therapy is contraindicated in bronchopneumonia with bronchitis of the opposite side and abundant expectoration. The age of the child, cyanosis and dyspnea are not contraindications.

Aseptic Purulent Pleurisy in Pneumonia in Children.—Stankiewicz reviews the various theories found in the literature with respect to pulmonary effusions in general and aseptic purulent extravasations in particular. The pathogenesis of aseptic pleurisy is not clear. It is found that in certain pathologic conditions of the lung (pneumonia, pulmonary congestion) and in pulmonary congestion consecutive to traumatism, in the infarcts, there appears a pleural complication in the form of purulent pleurisy. In aseptic effusions, the bacteriologic examinations are negative. Pleural puncture gives a yellowish, serous, bloody or purulent fluid; usually this purulent fluid is either white or yellow. Through decantation a fibrinous milky coagulum is formed. Centrifugation produces an abundant precipitate. Cultures as well as the inoculations into guinea-pigs are negative. Cytologic examination of the effusions is characteristic: there is a predominance of intact polymorphonuclear neutrophils, which are similar to those in the circulating blood and which have a homogeneous protoplasm and well stained nuclei with a distinct contour. When the disease lasts several days, the pleuritic fluid clears, and lymphocytes or eosinophils replace the original polymorphonuclear neutrophils. The character of the pleural fluid may vary at different times and the cytologic formula may sometimes also be mixed and include neutrophils, lymphocytes, desquamated endothelial cells, and eosinophils. Eosinophilia is frequent (sometimes to 60 per cent). It is rare that an aseptic effusion becomes septic. Aseptic effusions contain neutrophils that are intact and similar to the white cells of the blood. In protracted effusions, the cells are altered and the pleural fluid then contains half dead white cells. During a period of two years the author observed thirty-seven patients with ordinary pneumonia and eighty-nine patients with bronchopneumonia; 9 per cent of these had an aseptic effusion. The authors draw the following conclusions: The pleura plays a part in pulmonary congestion (pneumonia and bronchopneumonia) in children up to 3 years of age. Aseptic nontuberculous effusions are found in pneumonia as well as in bronchopneumonia in children. The effusions have a characteristic cytologic formula. In most instances they are small, benign and transient. The recognition of these exudates is important in prognosis and treatment.

Cholecystitis Due to Appendicitis. G. Lino.—p. 332.

Human Biliary Calculi and Their Absorption in Gallbladder of Dog.—Mirolli, confirming the experiments of Labes, obtained changes in the volume and the weight (fairly rapid and fairly conspicuous) of nonsterile human biliary calculi introduced into the gallbladder of the dog, sometimes normal and sometimes pathologically changed (not taken into account by Labes). He obtained also a diminution of weight, although slight, of biliary calculi, of the same chemical composition and same derivation, kept for two months at a constant temperature of 40 C. in dog bile collected from a biliary fistula. There was, however, such a marked difference between the changes in the calculi introduced into the gallbladder of the dog and those observed in the calculi kept in vitro in dog bile that, giving due allowance for the different chemical composition of normal bile and of fistular bile and for other considerations, he assumes that in determining the changes in weight and volume of the human biliary calculi introduced into the gallbladder of the dog there must be some cause involved that is associated with the living organism, which natually does not permit an experimental repetition of the phenomenon. He is inclined to postulate a true absorptive action peculiar to the mucosa of the bladder.

*Action Exerted by Solution of Pituitary and Insulin on Water Exchange Between Blood and Tissues and on Secretion of Urine. G. Pellegrini. —p. 1007.
Syphilis of Respiratory Apparatus, with Especial Reference to Pulmonary Localizations. P. Gerli.—p. 1045.

Action of Solution of Pituitary and Insulin on Water Exchange Between Blood and Tissues. — Pellegrini concludes from his researches that solution of pituitary exerts in cases of diabetes insipidus an evident action on water exchange between the blood and the tissues and also on the secretion of urine. The action of solution of pituitary on water exchange between the blood and the tissues varied in different cases. In two cases it provoked an increase of hydremia and a mobilization of the water reserves of the tissues. In another case it provoked a diminution of the hydremia and an increase of the water reserves. In another case it had no evident effect on hydremia. It reduced or retarded in every instance the concentration of the blood. In the tests on sodium chloride it was found to diminish the dilution of the blood. The action exerted on diuresis in the tests on the water exchange varied in different cases. In two cases, in connection with an increased hydremia there was observed an increase of urinary secretion. In one case there was a notable reduction of the diuresis, and in the last case there was no evident action. In the concentration tests, solution of pituitary always reduced the diuresis in evident manner. In the tests on sodium chloride it induced a reduction of urinary secretion in only one case; in the other cases it had no evident action. In the case in which, in connection with the administration of solution of pituitary there was observed a notable reduction of urinary secretion, there was a marked increase in the specific gravity of the urine. In the cases in which reduction of urinary secretion was not observed or was slight, the increase in the specific gravity of the urine was absent.

A Case of Fetal Inclusion. F. Rolando—p. 1298.

Search for Tubercle Bacillus in Gastric Contents of Children.—Zambrano searched for the tubercle bacillus in the gastric contents of fifty children, aged from 13 months to 12 years, with tuberculosis either clinically latent or manifested by clinical and roentgen symptoms in the lungs, serous membranes and the lymph nodes. The tubercle bacillus was encountered only eight times, and only once in children with absence of clinical signs of disease. In view of the rarity with which he found positive cases, the author considers that there is no reason for changing the conceptions heretofore held with regard to the evolution of tubercle bacilli in the infantile organism, since, with rare exceptions, tubercle bacilli are not found in the gastric juice of the infantile organism in selected cases; but he regards the method as more exact than the simple examination of the sputum.

Fat-Soluble Vitamins A and D in Treatment of Infectious Diseases of Childhood.—On the basis of the clinical observations cited, Flamini holds that the fat-soluble vitamins A and D administered in large doses exert a frankly beneficial effect on the course of infectious diseases in nursing children and in children recently weaned. The effect is in direct relation to the improvement in the local manifestations provoked by vitamin A, by its action on the inflamed mucosas (tonsils, bronchi, bladder), thereby stimulating the functional activity and the defense forces. The rapid drop and final disappearance of the fever may be due to the local curative action. It cannot be shown as yet whether vitamin A brings about the improvement in the general symptoms of the infection through an anti-infectious action or by an action stimulating the general defense forces of the organism. The improvement in blood pressure and pulse action may be due to vitamin D (administered in large doses) through the effect on the central nervous system and particularly the sympathetic system.

Preventive Vaccination with B C G Vaccine.—Malossi and Minghini affirm, on the basis of observations on 801 infants vaccinated at birth by mouth with the B C G vaccine and followed up for from one to five years, that this vaccine, if administered according to the prescribed method, is harmless. With regard to the protection afforded by the vaccine, they think it has an immunizing effect but that the effect is so weak that it is rarely revealed by skin reactions to the various types of tuberculin. One cannot rely on a constant and sure protective action of the method. Their researches leave untouched the question as to the harmfulness and the immunizing potency of the B C G vaccine when it is administered by the parenteral route.

*Incomplete Chronic Obstruction of Ileum and Multiple Ulcers. A. M. Centeno, D. Brachetto-Brian and P. A. Maissa.—p. 13.

Incomplete Chronic Obstruction of Ileum and Multiple Ulcers.—Centeno and his collaborators state that tuberculosis, cancer and occasionally syphilis have been considered, the causal factors of incomplete chronic obstruction of the small intestine. He reports a case in which all the conditions mentioned were absent, while the clinical symptoms and the roentgen examinations were characteristic of obstruction. At operation the presence of an inflammatory process (diffuse enteritis), causing a stricture at two different levels in the ileum at a distance of 24 cm. from each other, was discovered. The circumference of the ileum, which in normal segments was 6 cm., was 2.5 cm. and 4 cm., respectively, at the strictures, increased immediately above each stricture to 10 and 19 cm., respectively, and then became normal again. The mucous membrane of the narrowed areas was the seat of many simple ulcers. A segment of 70 cm. of the small intestine, including the narrowed ulcerous and dilated areas, was resected and an end-to-end anastomosis and appendectomy were performed. The patient did well. The roentgen examination made one month later showed complete reestablishment to normality in the intestinal tract. The author believes that the inflammation and the formation of ulcers were in his case the causal factors for the development of the strictures.

Syphilis and Tuberculosis in Infants: Mortality During First Year of Life. A. Romeo Lozano.—p. 661.

Congenital Stenosis by Hypertrophy of Pyloric Muscle in New-Born Infants.—Macein reports two cases of congenital stenosis by hypertrophy of the pyloric muscle in new-born infants aged 22 days and 5 weeks, respectively. The author advises thus: When the cause of vomiting and of loss of weight in new-born infants cannot be ascertained, the time of retention of the food in the stomach should be immediately determined, in order to substantiate or to rule out the diagnosis of stenosis caused by hypertrophy of the pyloric muscle. Lavage of the stomach, by proving the presence of food in the stomach, and roentgen examination of the stomach, by determining the retention of the barium meal given to the infant, are the only reliable methods to reach an early diagnosis of the condition. Early operation is the only hope to save the child's life for this type of stenosis. The roentgen examination made after the operation proves the normal passage of the food from the stomach to the large intestine. It is possible that stenosis caused by hypertrophy of the pyloric muscle is responsible for the death of many children who die with a syndrome of vomiting and undernutrition, and in whom a correct diagnosis is not made.

Clinical Case. G. Burbano.—p. 240.
*New Procedure for Treatment of Certain Hemorrhoids. A. Valerio.—p. 241.

New Procedure for Treatment of Certain Hemorrhoids.—Valerio recapitulates briefly some of the causes and treatments of hemorrhoids and presents a new procedure by which he has obtained twelve cures without any local or general complications. He uses any ordinary anoscope and any syringe with a needle of one centimeter. After infiltrating the base of each hemorrhoid with a 1 per cent solution of procaine hydrochloride, he injects into the submucous tissue, and then above the border of the base, 2 cc. of a freshly prepared and well shaken 2 per cent solution of trinitrophenol in double distilled water. Injections are repeated every week until three or four of the hemorrhoids are sclerosed, when the remaining ones disappear by a slow process of resorption. Patients are instructed to put themselves on a milk and vegetable diet for one week before the first injection and to insert every night a suppository of bismuth oxyiodide and resorcinol sulphonate or quinine and urea hydrochloride. The author recommends that particular care be taken to avoid the anterior commissure of the anosphincteric segment in order to respect the prostate gland. Sterilized petrolatum is the only dressing.

Carcinoma of Roentgen Technician Cured by Radium Therapy.—Roffo reports a case of ulcerated carcinoma from roentgen rays in the hands of a roentgenologist. The condition followed a slow evolution for ten years, causing definitely cancerous lesions and ulcers with great infiltration of the tissues. On account of the condition the patient was unable to work or to dress himself. Treatment with carbon dioxide snow, the high frequency current, and ultraviolet rays, failed. Radium therapy applied for about two months gave satisfactory results. The dose varied in the several lesions of the hands, the elbows and the fingers from 11 to 23 millicuries in each treatment given through a 1 mm. platinum filter. The radium therapeutic apparatus was retained "in situ" for periods which varied from 72 to 192 hours in each treatment. The lesions are cured, the hands are normal (with the exception of the scars left by the lesions) and the patient is able to work. Recurrences have not appeared one year later. The curative process of radium therapy is absolutely painless.

Blood Pressure Reflex and Hypertension.—Klink shows that the increase in blood pressure following compression of the upper arm during blood pressure tests is a generalized hypertension due to reflex action. This blood pressure reflex develops in the majority of patients with hypertension, especially in older patients, aged 60 or over, and also in patients with essential hypertension and renal insufficiency. Entirely different were the observations on young persons with hypertension but without other disease symptoms, for in these the reflex hypertension was absent. Electrocardiographic tests revealed that compression of the upper arm may produce changes in the auriculoventricular conduction system.

Metabolic Disturbances in Pellagra and Their Modification by Insulin.—In the introduction, Kaufmann-Cosla and his associates review the various theories of the pathogenesis of pellagra and especially Goldberger's studies, which indicated that pellagra is a metabolic disorder in which there exists a disturbance in the equilibrium between sugar, protein and fats and which can be prevented and cured by vitamin B. The authors' own investigations on the pellagra problem are summed up as follows: 1. In patients with pellagra there exists a serious disturbance in the general metabolism which manifests itself in dysoxidative carbonuria. 2. There is an increased elimination in the urine of the intermediate products of the sugar metabolism; namely, of acetic aldehyde and of lactic acid. 3. Insulin reduces the pathologically increased elimination of dysoxidative carbon, acetic aldehyde and lactic acid to normal values. 4. The metabolic disturbance involves primarily the carbohydrate group. 5. The pathologic changes of the urine, and the elective action of insulin on the general metabolic disturbances of pellagra patients justify the assumption that pellagra is closely related to avitaminosis, particularly to B avitaminosis.

Diagnostic Significance of Acid Soluble Phosphates in Blood in Coma.—Meier and Thoenes report that in true diabetic coma there is a reduction in the difficult hydrolyzable but acid soluble phosphoric acid esters. Inorganic phosphate is usually within normal limits and the entire acid soluble phosphates are correspondingly reduced. If in diabetic coma the inorganic phosphate is increased, a simultaneous uremic disturbance must be assumed. In uncomplicated uremia the inorganic phosphate is always considerably increased and the difficult hydrolyzable esters are reduced only in cases with marked hydremia; accordingly, the entire acid soluble phosphate is normal or increased. If in comatose conditions with simultaneous glycosuria and acetonuria there are normal phosphate fractions, it should be considered that a diabetic coma is not the only cause. If in comatose conditions with glycosuria and acetonuria the inorganic phosphate is increased, but the esters and the entire acid soluble phosphate are normal, diabetes is not the only cause of the condition but it is probable that a uremic disturbance is the cause of the comatose condition.

Treatment of Hay Fever by Desensitization.—Hansen admits that although theoretically a strictly specific desensitization is advisable, its practical application is extremely difficult. He therefore tried the efficacy of a mixed extract, which contains the pollen of the most common varieties of grass, which in Germany are the main cause of hay fever. With this extract he effected complete freedom from symptoms in 16 per cent of the cases, considerable improvement in 40 per cent, moderate improvement in 20 per cent, and failure to improve in 24 per cent of the cases. This proves that for the majority of hay fever patients the mixed extract is satisfactory. A strictly specific treatment is necessary only in those cases in which, according to the anamnesis and to the cutaneous reactions, pollen from plants other than grasses are the cause, or pollen from such grasses not included in the mixed extract. For patients that are refractory to the ordinary treatment the author recommends either desensitization with larger doses or the so-called chronic desensitization.

Injectable Liver Extract in Treatment of Pernicious Anemia.—Meythaler gives the clinical histories of nine patients with pernicious anemia, who were treated only with injectable liver extract. The treatment produced favorable results in all cases. However, secondary anemias could not be influenced by the injectable liver extract. In regard to the dosage, it is stated that relatively small quantities are sufficient. In the beginning 2 cc. is injected daily, and this has the therapeutic effect of 500 Gm. of fresh liver in oral administration. Later, from one to two injections every week may be sufficient, depending on the blood status. The injection is especially valuable in patients who have an aversion to oral liver therapy. It also makes blood transfusions unnecessary.

*Simple Method for Quantitative Determination of Sugar in Urine. L. Dinkin.—p. 1793.

Fat Diet and Carbohydrate Tolerance.—Adlersberg and Porges call attention to the fact that until recent years fat was one of the main substances in the diabetic diet, and the proteins and carbohydrates were restricted. The authors were able to show, however, that reduction of the carbohydrate intake accompanied by increase in the fat intake impairs the carbohydrate tolerance. In recent years a change has taken place in the nutrition of diabetic patients in that a greater amount of carbohydrates is permitted; however, the advice for a limitation of the fat intake has not been heeded. As a new proof for the diabetogenic action of a fat diet the authors cite their tests on normal persons, which revealed that if a larger amount of fat is given on the day preceding a sugar tolerance test the sugar tolerance is considerably reduced; moreover, tests on partially pancreatectomized dogs and observations on diabetic patients prove the same. As additional evidence that a large fat intake is a causal factor in diabetes, the authors cite the observation that diabetes is most frequent in countries in which the per capita consumption of fat is greatest. In the last part of the article they show that the essentials of their dietary treatment of diabetes are often misunderstood in that some designate it as a protein diet. However, the reason why comparatively large quantities of protein are given to obese diabetic patients is its great satiating value. However, the antidiabetic factor of such a diet is not the high protein content but rather the deficiency in fats. The large amount of protein is often given because insulin treatment is to be avoided, and because of this, not sufficient carbohydrates can be given. In these cases the high protein content of the diet is only a makeshift; it would be better to give large quantities of carbohydrates with simultaneous insulin therapy.

Simple Method for Quantitative Determination of Sugar in Urine.—Since modern treatment of diabetes necessitates constant control of the patient's urine, and since the fermentation method as well as the polarimetric procedure is too complicated for use by the general practitioner, Dinkin recommends Nylander's test for the quantitative determination of the sugar content of the urine. He states that the length of time that is necessary for a complete black coloration (in sufficiently diluted solutions) indicates with considerable exactitude the percentage of dextrose.

Massive Salicylate-Alkali Method in Treatment of Acute Articular Rheumatism.—Danielopolu and his associates maintain that the only specific remedy for acute polyarthritis rheumatica is salicylic acid. No other preparation is quite as effective. Sodium salicylate causes, even when given in small doses, manifestations of intolerance such as tinnitus aurium, gastric disturbances, impairment of the general condition, restlessness and occasionally tachycardia, dyspnea and semidelirium. In testing the alkali reserve and the p_H content of the blood and of the urine it could be proved that the intolerance manifestations are due to a marked acidosis. It was also found that all these manifestations disappear within twenty-four hours if the patients are given the same doses or still larger ones of sodium salicylate with an addition of the double amount of bicarbonate for each gram of salicylate. Simultaneously with the disappearance of the symptoms, the acidosis decreases, and the alkali reserve of the blood may even be in excess of that previous to the treatment. The usual doses of sodium salicylate (4, 6, 8 Gm.) are insufficient. If such doses are given, the fever and the articular manifestations persist and cardiac localization is almost certain. The rheumatic infection attacks the myocardium if the salicylate treatment is insufficient, but it becomes manifest much later in the form of an advanced degeneration of the myocardium, which borders on insufficiency. Valvular lesions are rarer and are always accompanied by lesions of the myocardium. In the massive salicylate-alkali method one adheres to the following rules: 1. The doses of sodium salicylate have to be large, up to 25 Gm. daily. 2. The treatment has to begin early and the doses should be increased rapidly up to the maximum. The maximal dose has to be continued until all symptoms have disappeared, and the reduction of the doses should be gradual and slow. 3. The maximal daily dose for cases of medium severity is 15 Gm. and for severe cases 25 Gm. 4. The treatment has to be continued for weeks and even for months according to necessity. 5. The total daily dosage should be divided so that a portion is administered at intervals of two hours during the day and at intervals of four hours during the night. 6. Each portion should be dissolved in 100 Gm. of water, and after every administration nourishment should be given. 7. An antiketogenic diet is advisable (especially sweets and farinaceous foods). 8. Alkalization of the organism is to be effected by giving quantities of sodium bicarbonate double those of salicylate. In enumerating the advantages of the massive salicylate-alkali method, the authors stress that this form of medication does not cause gastric or nervous disorders, even if it is continued for longer periods. Only in rare cases do extrasystoles develop.

Fever and the articular symptoms yield more readily to this than to any other method. New cardiac lesions are also influenced to a certain extent and the massive salicylate-alkali method is the only one that prevents the development of chronic cardiac lesions.

Etiology of Funicular Myelitis.—Kúnos shows that acute or chronic gastro-intestinal disorders are of great significance in the etiology of funicular myelitis. The various forms of these disorders of the intestinal tract usually have one symptom in common, namely, gastric achylia. Autointoxication as a result of changed conditions in the resorption is therefore assumed as the pathogenic factor of funicular myelitis. This assumption is closely related to Seyderhelm's theory of pernicious anemia. But the author extends this theory in that he maintains that the unknown noxa assumed by Seyderhelm not only causes anemia but also influences the nervous system, and the result of this influence is funicular myelitis.

Prognosis of Primary Chronic Articular Rheumatism.—In the introduction, Schneyer deplores the confusion in the nomenclature of rheumatism. He points out that cases of polyarthritis deformans and of infectious arthritis are sometimes listed under rheumatoid arthritis. He thinks that it is due to this confusion that focal infection is still considered as a cause of primary chronic articular rheumatism. That this is not the case, at least as far as the tonsils are concerned, he was able to prove by the ineffectiveness of tonsillectomy. A review of the literature indicates that the prognosis is generally considered as unfavorable. However, the results of the after-examination in 140 patients convinced the author that the prognosis is not as unfavorable as is often believed. He gained the impression that early and persistent treatment may produce favorable results. Since the prognosis of a disease is largely determined by the therapy, he discusses the treatment. Because the etiology of primary chronic articular rheumatism is still unknown, a causal or specific treatment is not possible. In the majority of the patients on whom the author made his studies, the usual physical and medicinal treatments had been employed. Most effective was radium therapy, given in the form of inhalations or of radioactive applicators, and also roentgen therapy. These treatments reduce the painfulness, improve the function of the joints and improve the general condition. However, there are also cases that are refractory to radium therapy. Foreign protein therapy is effective in many cases, provided the correct technic is employed. In order to prevent muscular atrophy, deformation of the joints and ankylosis, electrotherapy and massage should not be neglected. To counteract the anemia and the general weakness, which often develop in the course of primary chronic articular rheumatism, the author recommends arsenic preparations. He advises against weakening dietary treatments and rejects tonsillectomy. During the exudative stage he considers immobilization advisable, but he warns against leaving on a fixation bandage too long. He recommends the use of appliances that protect the joint but, by rendering possible suitable exercise, prevent ankylosis and muscular atrophy. In the conclusion the author stresses once more that the unfavorable prognosis assumed by many for cases of primary chronic articular rheumatism is not justified but that by a suitable therapy many patients can be cured.

Therapy of Colitis Gravis by Production of Anaphylaxis.—The term colitis gravis is, according to Kalk, still justified, since it is refractory to most therapeutic measures and consequently has an unfavorable prognosis. However, he found that it can be improved or completely cured if it is possible to induce by means of serum injections a marked anaphylactic reaction with cutaneous manifestations. He gives the case histories of eight patients who were treated in this manner, in five of whom it was completely effective, whereas in three cases the production of serum disease proved impossible. In the intentionally produced anaphylaxis it was also possible to make certain observations on the essentials of serum disease. The curative effect of anaphylaxis on colitis gravis could be proved not only by the clinical observations but also by roentgenologic examination of the colon, especially by the relief visualization of the mucous membrane. Transfusion of large quantities of blood also proved helpful in a number of cases of colitis gravis, eight of which are reported. However, the results were not quite as favorable as those produced with anaphylaxis. The author recommends that in colitis gravis transfusion of large quantities of blood should be tried first, and if this proves ineffective the artificial production of serum disease should be resorted to.

Estimation of Pulmonary Tuberculosis by Sedimentation, Blood Picture and Coagulation.—In summing up their observations, Weltmann and Paula state that the sedimentation reaction, the hemogram and the coagulation test are all helpful in estimating pulmonary tuberculosis. Considering the chronic course of pulmonary tuberculosis, it is evident that estimates should be based only on repeated tests and if possible on serial tests. In regard to the final outcome of the tuberculous process, the hemogram gives the most reliable information. Increased sedimentation speed, especially if it persists, indicates the necessity for careful supervision, even if the clinical manifestations of the process are comparatively slight. However, it should also be considered that it may be a false alarm. The sedimentation test is of value particularly in acute cases with slight physical signs and in not too severe chronic cases, which should be kept under observation as long as the sedimentation speed is increased. The coagulation test is still too new to permit its definite evaluation. However, in connection with the clinical aspects and with the two other methods it gives valuable information, especially about the tissue changes. A reduction of the coagulation to subnormal values indicates the prevalence of exudative processes, whereas a prolongation indicates fibrous tendencies. If the coagulation is not in accord with the clinical and the general aspects, the sedimentation reaction and the hemogram should serve as controls.

Sarcoma of Tongue. H. Kudlich.—p. 99.
Influence of Cold on Transplantability of Tumors, on Blood Coagulation and on Complement Action. H. Auler.—p. 103.

Cancer as Disease of Entire Organism.—Larionow thinks that a malignant neoplasm is not merely a local disease but that it is essentially a disturbance in the regulatory system of the organism. If special cell groups are present, there develops, because of these disturbances, a physiologic isolation, and finally the cells lose their correlation capacity. The malignant neoplasms are therefore to a certain degree local manifestations of a generalized disorder. However, for the development of these manifestations it is necessary that certain local processes develop first. To consider the generalized changes in the organism merely as a "predisposition" is inadequate for the reason that these changes are a component of equal importance.

Bismuth in Treatment of Tumors.—Zadik points out that he as well as numerous other investigators has proved that water soluble bismuth compounds have a curative effect on malignant tumors. In order to understand the action mechanism of bismuth therapy of malignant tumors he made further experiments, and he gives the following summary of his observations: 1. The elective storage of bismuth in the tissue of malignant tumors is traced to the biochemical reaction of the metal with the lactic acid. This chemical union is also the cause of the specific focal reaction, which was observed following administration of bismuth compounds. 2. Application of radium E according to Kahn-Klopfer makes it possible to direct the radium action by way of the blood stream into the tumor, because this type of radium, being isotopic to bismuth, has likewise a tendency for elective storage in the tumor. 3. There is yet another possibility to bring radium to the tumor cells, namely, by combining radon with colloidal bismuth solutions. With this procedure it is possible to concentrate intensive alpha action on the tumor. 4. Radon may also be combined with colloidal dyestuffs such as trypan blue, isamine blue and bengal rose, for these substances likewise have an elective affinity and perhaps also an influence on the tumor cells.

***Predisposing Factors in Experimental Inoculation* Tumors.**—Geréb observed in experiments that the growth of tumors can be influenced by nutrition and by hormonal conditions, but he was not able to demonstrate definitely that these factors have an influence on the "taking" of inoculation tumors. A diet, deficient in vitamins and consisting mostly of neutral fats, had the greatest inhibitory influence on the growth. Gravidity and lactation likewise exerted a growth inhibiting influence.

Pribram's Operation in Diseases of Gallbladder.—Pop calls attention to Pribram's operation, which was first described by Pribram in the *Medizinische Klinik* (**24:**1147 and 1187 [July 27 and Aug. 3] 1928; abstr. The Journal, Oct. 6, 1928, p. 1070). He reports the results of this operation in thirty-six cases and concludes that Pribram's operation, which is characterized by thermo-electro-coagulation of the gallbladder, and which eliminates abdominal drainage, gives good results and should be employed in all cases in which the gallbladder cannot be extirpated without injuring the bed of the liver and the surrounding organs, yet he extends the indication for Pribram's operation even further, in that he advises it for all cases in which subserous extirpation is impossible. He also states that it can be performed on patients of all ages and during an attack of gallbladder disease as well as during the interval. In summing up the advantages of Pribram's operation he mentions again the avoidance of injuries of the liver bed and the elimination of abdominal drainage, which does away with postoperative adhesions. He further stresses that the preservation of the gallbladder prevents the formation of biliary fistulas, and that the heat or the electric current destroys the infectious foci in the wall of the gallbladder and in the perivesical liver tissues. All thirty-six cases observed by the author healed without complications.

*Congenital Cysts of Pancreas. M. B. Ariel.—p. 705.
*Phrenic Phenomenon in Appendicitis. V. A. Vainov.—p. 709.

Water Tolerance Test in Study of Hepatic Function.—Rapoport asserts his observations led him to conclude that the intake of 1,500 cc. of water does not influence the rate of sedimentation of erythrocytes in a normal individual. In patients with hepatic disturbances such a volume of water causes changes in the rate of sedimentation. The changes in the rate of sedimentation after overloading with water are dependent on the capacity of the liver to concentrate and can therefore be valuable in diagnosis. These are problems in changes in the physicochemical properties of the circulating blood.

Congenital Cysts of Pancreas.—Ariel asserts that pancreatic cysts may be present without manifesting any clinical symptoms during the life of the individual, and may not be discovered unless other pathologic factors have called for surgical intervention. The author describes one instance from the literature and his own personal observation. His patient was a woman, aged 64, with a clinical diagnosis of diabetes mellitus and pneumonia dextra inferior. The microscopic observations at necropsy were comparable to other instances described in literature. These cysts of the pancreas are not adenomatous but dysontogenetic cysts and similar to those found in the liver and kidneys. In accordance to other reports, microscopic examination demonstrated hemorrhagic infiltration between the cysts. Various phases of cystic development were noted: these ranged from sanguineous cysts to those designated in the literature as "cystenleichnama" or cadaver cysts. The author concludes that pancreatic cysts should be included among other congenital cysts and that the spreading cysts may interfere with pancreatic secretory function over a long period of time. One worker reports that the cysts interfered with metabolism in two breast-fed infants. Pancreatic cysts are usually silent and never cause an acute condition. Sugar in the urine of the patient described by the author was not entirely due to the described anomaly, since only one fourth of the pancreas was cystic.

Phrenic Phenomenon in Appendicitis.—Vainov based his report on the results of the examination of 197 patients, 93 of whom were subsequently appendectomized. He concludes that the phrenic phenomenon is present in the majority of patients with appendicitis. Although this phenomenon cannot be considered pathognomonic, it should nevertheless be included among the other symptoms of the clinical picture.

*Complicated and Uncomplicated Bronchopneumonias. A. Friedlænder.—p. 1174.
Case of Benzine Intoxication with Fatal Outcome. O. L. Nielsen.—p. 1178.

Complicated and Uncomplicated Bronchopneumonias.—Friedlænder's 590 cases of bronchopneumonia were mainly in children in the first two years of life and from the poorest families in Copenhagen. Of the 370 cases in the first year of life, 26.5 per cent were fatal; of the entire number, 22 per cent. He finds that factors such as nutrition and earlier diseases, especially rickets, do not seem in this relatively large material to play the part suggested by experience, and study of still larger materials is urged, to verify or reject these results, which bear on the causes of death in early childhood.

THE SEMINAL VESICLES

NEWER INSTRUMENTAL METHODS IN DIAGNOSIS AND THE THERAPEUTIC MANAGEMENT *

JOSEPH F. McCARTHY, M.D.
AND
J. SYDNEY RITTER, M.D.
NEW YORK

While instrumentation of the ejaculatory duct and seminal vesicles was done by Klotz as long ago as 1885, and though many serious studies have been published on the subject, it may reasonably be asserted that the precise status of the seminal vesicle as a factor in disease remains to be determined.

Our objective, therefore, in this communication, one of a series of correlated researches which may be considered in the main as preclinical studies, has been, by means of improved and rational technical procedure, to render the seminal vesicles accessible to the same kind of study as, for example, is now the renal pelvis: in other words, to bring it within the spotlight—the searching scrutiny of orderly scientific investigation.

In the majority of our cases we are able to catheterize the ejaculatory ducts with the same type of catheters as are employed in ureteral work; in many of these, to obtain seminal vesicular secretion uncontaminated with prostatic secretion; to subject this isolated seminal vesicular secretion to microscopic and cultural investigation; to make routine seminal vesiculographic exposures, and, in cases indicating it, to perform synchronous ureteropyelographic and seminal vesiculographic exposures of the same side.

To understand the subject matter better, one must thoroughly familiarize oneself with the anatomy of the parts. The ejaculatory ducts average 15 mm. in length and 1.9 mm. in circumference. As they extend backward through the verumontanum and prostate gland, the lumen becomes larger until their division into the duct of the seminal vesicle and ampulla of the vas deferens, at which point the average circumference is 4.5 mm. At the orifice, the lumen is slit-like and as they progress through the prostate gland it becomes elliptic, the greater diameter being vertical; at their termination, the lumen is circular.

The course of the ejaculatory ducts is as follows: they take a very sharp dip through the verumontanum from the urethral orifices, at an angle of approximately 45 degrees to the urethral floor. For the first millimeter and a half the ducts diverge and then converge for the next millimeter or two, until there is a thin septum of fibrous and elastic tissue separating them. This wall is easily penetrated, even though soft, flexible instruments are used. They then run parallel to each other and usually at a less acute angle through the prostate gland, ending at the termination of, or within the substance of this gland. This anatomic deviation would seem to emphasize the unsuitability of rigid instruments and to justify their replacement with flexible catheters. This separating membrane is so friable that we have observed, in one or two instances, the introduction of a number 4 ureteral catheter in one side followed by the injection of an opaque medium, to result in a vesiculogram of the opposite side.

The lumen of the duct of the seminal vesicle measures 4.5 mm., whereas the lumen of the ampulla of the vas deferens has a circumference of 3.1 mm.; noting the circumference of the ejaculatory duct at its termination, these measurements may somewhat confuse one. The similarity in size of the lumen of the ejaculatory duct with that of the seminal vesicle is accounted for by the fact that the ampulla opens on the mesial aspect of the ejaculatory duct. The duct of the seminal vesicle is a direct continuation of the ejaculatory duct, whereas the ampulla is a tributary. This anatomic fact explains why the ejaculatory duct catheter enters the first saccule of the seminal vesicle and in none of our cases was seen to enter the ampulla of the vas deferens. This is contrary to the opinion expressed by Young. The seminal vesicle in every instance was distended prior to the ampulla of the vas deferens and vas, when solutions were injected through the ejaculatory duct. In several of our cases not alone were the seminal vesicle, ampulla of the vas deferens and vas injected, but even the tubules of the epididymis were visualized. This fact does not coincide with the opinions of Belfield and Rolnick.

APPARATUS AND TECHNIC

To facilitate the catheterization of the ejaculatory duct, it is essential that an instrument be used which will direct the catheter to take the same relative course that the ejaculatory duct takes through the verumontanum and prostate gland. For this purpose the McCarthy ejaculatory duct catheter carrier, with spring wheel deflector, is necessary.[1] It is composed of three parts, the sheath, obturator, panendoscopic telescope and the ejaculatory duct catheter carrier. The sheaths are a number 24 F. and a number 26 F. whose circumference is more circular than the ordinary panendoscopic sheath. The telescope is slightly modified to admit this carrier, a new departure in urology, for with its use catheterization of the ejaculatory ducts and therapy to the seminal vesicles in indicated cases is rendered a simple procedure.

---

* From the Department of Urology, New York Post-Graduate Medical School, Columbia University.

* Read before the Section on Urology at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 12, 1931.

[1] This instrument would not have been possible but for the inventive genius of Mr. Reinhold Wappler of the American Cystoscope Makers, Inc., New York.

There are two fixed channels through which a number 4 and a number 6 F. catheter can be passed. The distal end of the carrier with its spring roller deflector directs the catheter in the same relative course that the ejaculatory duct takes through the verumontanum. The proximal end is constructed so as to permit the rotation of the telescope whereby the catheter and the ejaculatory duct orifice may be brought into view without the necessity of rotating the outer sheath, decreasing to a minimum the possibility of traumatizing the verumontanum. A soft flexible ureteral catheter is introduced into the ejaculatory duct orifice and the instrument rotated, directing the catheter toward the lateral wall of the duct, which is firmer and less easily penetrated than the thin friable septum between the two ducts. It is necessary to tilt the instrument to an angle of approximately 45 degrees so that the catheter may take a downward course, avoiding penetrating the posterior aspect of the verumontanum. After the catheter has been passed 2.5 cm. or more and the eyes of the catheter are within the lumen of the ejaculatory duct, it is reasonable to expect to obtain some of the uncontaminated seminal secretion. After a few moments, should no secretion appear, it is permissible to inject 1 cc. of sterile saline solution, which will dilute the viscid seminal secretion permitting it to flow through the catheter. At this time, should a vesiculogram be desired, a 5 cc. syringe containing 5 cc. of a radiopaque solution is connected up with the catheter by a hypodermic needle. After 1.5 cc. of the solution has been injected, the medium may be seen returning from the seminal vesicles about the catheter at the ejaculatory duct orifices. This does not signify that the seminal vesicle is completely distended. It is best to continue the injections until 5 cc. has been introduced so as to replace the vesicular secretion or become a homogeneous mixture with it casting a shadow.

To aid further in the visualization of the seminal vesicles and its ducts, the emptying of the bladder of all solutions and the introduction of 100 cc. of air is of great value. In order to avoid the overlapping of the seminal vesicles by the pubic arch, the patient's shoulders should be raised about 10 degrees from the table and the x-ray tube left in the usual position while the exposure is being made.

Various opaque solutions have been advocated for vesiculography, including colloidal silver and iodized oil. In our experience, sodium iodide, colored with a dye of either indigo carmine or methylthionine chloride, U. S. P. (methylene blue), in as concentrated a solution as 30 per cent, has been found to be most satisfactory. This solution causes little or no irritation unless extravasation occurs. In the few instances in which this has occurred, no untoward effects have been noticed. The colored solution permits one to note the escape of the solution at the orifice of the ejaculatory duct.

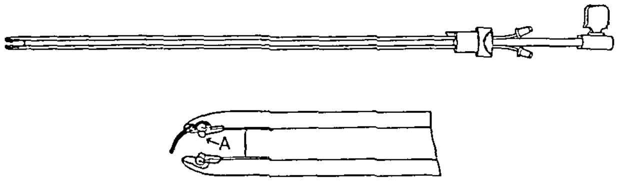

Fig. 1.—McCarthy ejaculatory duct catheter carrier: *A*, spring roller used for deflecting catheter.

Since 1925, we have studied several hundred seminal vesicles with the hope of arriving at a definite conclusion relative to determining the appearance of a normal seminal vesiculogram. It was therefore thought advisable to obtain cultures of the seminal secretion, examine this secretion microscopically, and make notations relative to the rectal observations, noting at the same time any pathologic conditions existing in the epididymis or vas deferens which would aid in diagnosing a case of seminal vesiculitis clinically.

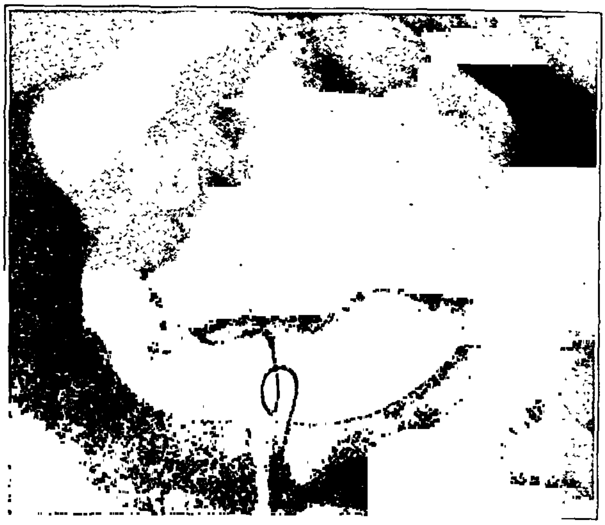

Fig. 2 (patient S.).—Catheter coiled in right seminal vesicle: seminal vesiculogram demonstrating some congenitally large saccules with abnormal dilated saccules of the ampulla.

SUMMARY OF FIFTY CASES

According to the investigation of Habute, there are definite changes in the appearance of the seminal vesicles at the various decades of life. We have vesiculograms in adults ranging from the ages of 21 to 56 but were unable to ascertain any appreciable anatomic changes referable to this expanse of thirty-six years. We have had the good fortune of seeing the seminal vesicles of the new-born and on through life up to and over the alloted three score years and ten, and noted no changes particularly significant in any decade of life other than growth.

Of the vesiculograms here presented, fourteen were normal. These conclusions were drawn from the fact that the individual saccules were definitely outlined. The ejaculatory ducts, ampulla of the vas deferens and, in some instances, even the epididymis, was seen to be injected. Cultures obtained were negative; microscopic examination of the seminal secretion was negative. The presenting symptoms were not referable to a vesiculitis.

To consider the seminal vesicle normal it is necessary to note a homogeneous distention of the individual saccules, the definite outlines of which are; demonstrated. Uncontaminated cultures obtained from the seminal vesicles were reported negative. Microscopic examination of the seminal secretion was also found negative. It was thought advisable to determine the emptying time of the normal seminal vesicle. For this purpose roentgen exposures were made one and two hours after the injection. It was found that normally the seminal vesicle was empty after two hours. This should not lead one to conclude that the seminal vesicle is constantly draining; we feel that a peristaltic contraction is produced as the result of the injection of a foreign substance, and for this reason the vesicle empties, as stated. The hypertonicity of the injected medium is probably the underlying factor here.

Congenital defects or arrests were noted in six cases.

In Sargent's report he states that the seminal vesicles are alike on the two sides and that when there is a difference in the two sides it may be concluded that a pathologic condition exists on one side. Case 45 shows a definite congenital arrest as compared to the opposite side. This patient gave no symptoms referable to disease of the seminal vesicles, nor have we clinically been able to note any pus or organisms present, nor any rectal evidences of disease. We have noted that this case, plus several specimens examined at autopsy, showed variations of the two sides.

There were six cases of a large, atonic type of seminal vesicles from which the secretion was found to be negative to culture and microscopic examination; these were in individuals presenting symptoms of spermatorrhea with a history of prolonged masturbation.

There were thirteen cases of chronic seminal vesiculitis demonstrating the contracted and dilated type.

The contracted type of chronic seminal vesiculitis seen in seven cases showed the ejaculatory duct normal, the saccules of the seminal vesicles incompletely distended, some apparently occluded and no evidence of dye present. However, some of the saccules are sharply defined with definite decrease in size. The large patulous type of chronic seminal vesiculitis again demonstrates a fairly normal ejaculatory duct. However, the individual saccules of the seminal vesicle are dilated.

One instance of a large chronic seminal vesiculitis causing definite pressure on the lower end of the ureter gave evidence of obstruction to the overflow of urine, the patient presenting symptoms referable to ureteral colic.

One case of acute urinary retention occurring in a young subject was found to be due to enormously enlarged seminal vesicles.

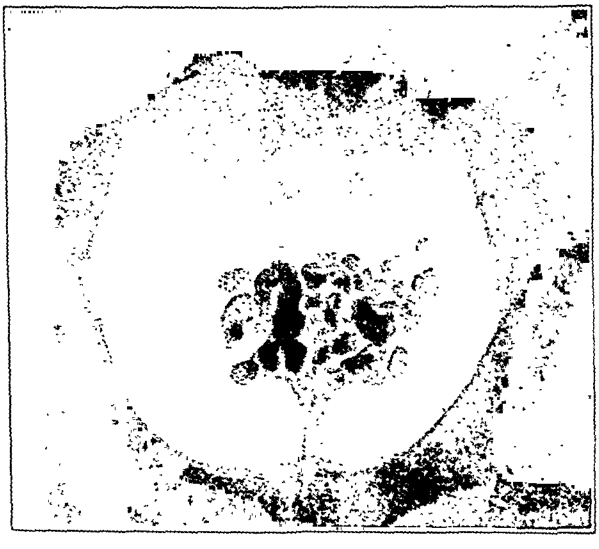

Fig. 3.—Bilateral normal vesiculogram demonstrating ejaculatory ducts, ampulla of the vasa, seminal vesicles and vasa of M. C., a man, aged 31, treated for urethritis, who complained of a slight morning urethral discharge. Smears were negative. Specimens obtained from the seminal vesicles showed living spermatozoa. No pus cells. Cultures were negative.

It is possible to have a chronic inflammatory condition causing anatomic changes in all or part of the seminal vesicles; in other words, the proximal saccules may show pathologic changes, whereas the distal saccules will be normally outlined, and vice versa. There were two cases of gonorrheal arthritis in which the vesiculogram showed changes which were interpreted as subacute seminal vesiculitis because of the fact that the vesiculograms were on the borderline with the seminal secretion containing clumps of pus.

There was one case of proved tuberculous seminal vesiculitis with abscess; this case, through discussion as to the proper interpretation, led one of us to do a vasotomy and inject our material in this manner. On roentgen exposure the solution was seen to outline the vas up to a fixed point and then extravasate into the abscess cavity, confirming the opinion that a solution in the continuity of the lumen of the vas deferens had occurred. There was an interesting case of sterility in which catheterization of the ejaculatory ducts yielded brown pigmented material in which numerous nonmotile spermatozoa were seen. When the opaque medium was injected and a vesiculogram obtained, there was a definite dilatation of the ejaculatory duct, which was due to a partial occlusion of the ejaculatory duct lumen.

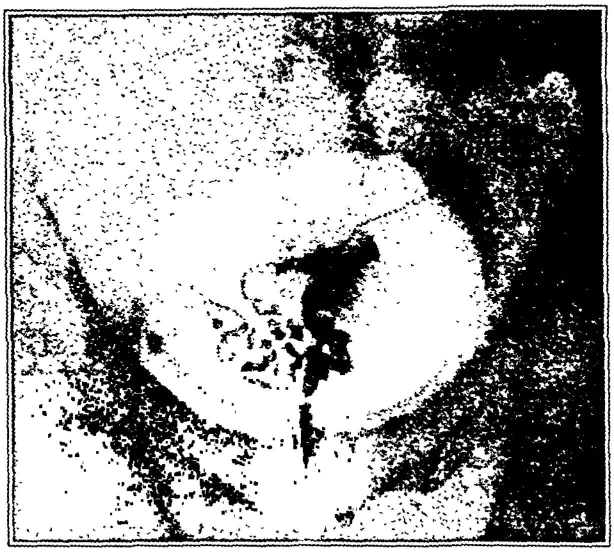

Fig. 4 (patient H.).—Congenital tubular type of seminal vesicle with evidence of chronic dilated seminal vesiculitis of the left seminal vesicle.

In twenty cases we were successful in obtaining seminal secretion for examination, and on culture a nonhemolytic streptococcus, Streptococcus viridans, Staphylococcus albus, a diphtheroid organism and Staphylococcus aureus were found. An unidentified gram positive coccus was reported on several cultures. Von Lichtenberg stated that he found a similar organism in his studies. In five cases, though pus cells were demonstrated in the smears, cultures were negative. In one case, definitely proved to be tuberculous, no organisms were seen in the secretion. We can only assume that in a good number of the negative cultures the gonococci, which should be most frequently encountered, were not obtained. This is probably due to faulty technic in the use of the culture medium.

COMPLICATIONS

In a small percentage of our patients, subacute epididymitis occurred. This usually appeared twenty-four hours after instrumentation. However, it was not as severe as the epididymitis caused by infection, and usually subsided in thirty-six hours with mere support. In none was there evidence of acute hydrocele. The epididymis itself was enlarged, tender—not acutely so—

with no evidence of accumulation of fluid in the tunica vaginalis. In no instance did this condition progress further than that of a chemical epididymitis. In no case have we observed residual nodulation.

A second complication is that of extravasation of the iodide into the surrounding tissues. The patient complained of severe pain as soon as it occurred and injection was stopped immediately. Within ten minutes after removal of the instrument, all pain had subsided and no untoward complications were noted on subsequent examination.

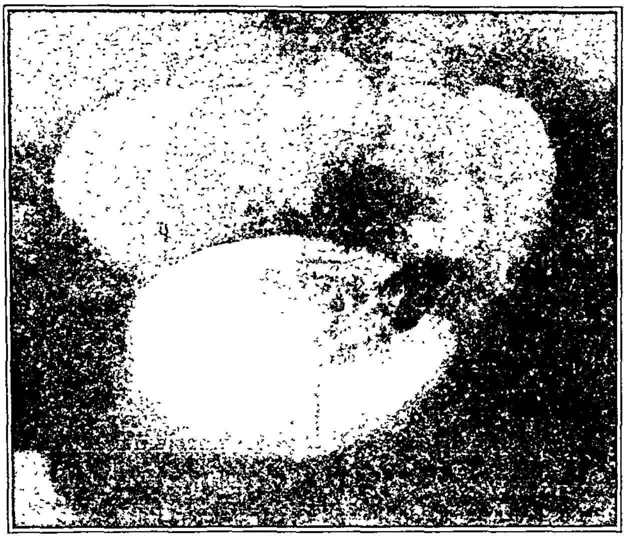

Fig. 5 (patient S. S.).—Seminal vesicle approximal sacculations definitely outlined; cephalic saccule confluent and smooth. Culture shows Bacillus coli. The epididymis is definitely outlined in this picture. Diagnosis, chronic seminal vesiculitis.

These are the only complications encountered, and it is therefore fair to assume that this procedure is a safe, rational diagnostic and therapeutic measure.

Contraindications to any type of urethral instrumentation should be considered as the only objections to vesiculography.

INDICATIONS FOR VESICULOGRAPHY

Catheterization of the ejaculatory ducts together with the collection of the uncontaminated seminal secretion, generally speaking, should be reserved for refractory cases of seminal vesiculitis not responding to the usual therapeutic measures. The specific indications are as follows:

1. Chronic arthritis—when other foci have been eliminated and the seminal vesicles are suspected.
2. Persistent chronic posterior urethritis with evidence of verumontanitis and microscopic evidence of pathologic changes in the expressed secretions.
3. Vague indefinite backaches—undetermined by the usual measures.
4. Impotentia.
5. Sterility.
6. Sexual asthenia with large palpable vesicles to determine patency of the ejaculatory ducts.

CONCLUSIONS

1. The seminal vesicles are a possible focus of infection.
2. This new ejaculatory duct catheterizing endoscope has rendered catheterization of the ejaculatory ducts a routinely feasible procedure.
3. Vesicular secretion, uncontaminated by prostatic secretion, is obtainable for chemical and bacteriologic study.
4. Seminal vesiculography is a diagnostic aid.
5. Seminal vesicular lavage is a practical procedure.
6. The ampulla of the vas deferens is lavaged when solutions are injected by any of the ejaculatory ducts.
7. Medication administered through the ejaculatory duct in some instances reached the tubules of the epididymis.
8. In cases of incomplete drainage of the vesicle, gradual dilation with small, soft, flexible bougies or catheters was of greater value than any procedure heretofore advocated.
9. The contour of the seminal vesicle is changed as the result of pathologic conditions.
10. Ejaculatory duct catheterization plus vesicular lavage definitely relieves symptoms.
11. Seminal vesiculitis may cause ureteral obstruction.

Though these studies have been basic and preclinical in character, certain interesting observations have been noted and a few experimental studies essayed. The most frequent question asked by our colleagues has been "What solution do you employ for vesicular lavage?" The answer is that we have purposely deferred this study until the completion of the present work. Incidentally, however, it has been observed on a number of occasions that obscure backache or perineal pain was completely relieved by the passage of the catheter in the taking of a vesiculogram.

In conjunction with Dr. John A. Killian, director of biochemistry, and Dr. C. Travers Stepita of our department, studies were made of the relative motility and viability of the spermatozoa. In this investigation motility was experimentally inhibited. It was then found that, by the addition of various biochemical solutions, they could be revitalized and their normal motility restored and increased.

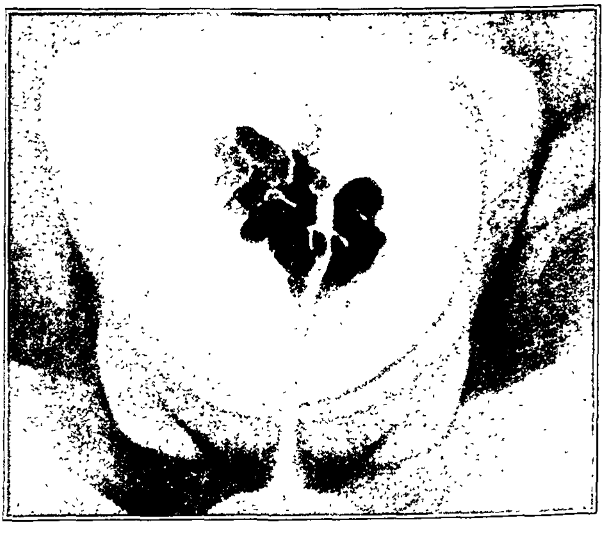

Fig. 6 (patient G.).—Chronic left seminal vesiculitis: *Bilateral vesiculogram* in a patient presenting a history of left epididymitis in whom smears show many pus cells from the left seminal vesicle. Left vesiculogram shows a failure of filling of cephalic saccule due apparently to either occlusion or pus.

From these studies it was deduced that, by the introduction of such solutions into the vesicles of the patient with sluggishly motile spermatozoa, their normal motility could be restored in vivo.

Furthermore, it was thought that through the use of these solutions, proved so favorable to the motility of the sperm, normal spermatic fluid could be diluted with such solutions, thus rendering it possible to inject this mixture directly into the vesicle. This has been carried out in a small series of patients, in some of whom normally active spermatozoa have later been recovered.

This study is of too recent origin for us to assert that fertility may thus be simulated by the azoospermic vesicle; rather is it our intention to make its technical feasibility a matter of record.

Intra-uterine instrumental insemination has, for obvious reasons, been most disappointing in its failures. This method of what might be called two-stage insemination, with its accompanying physicopsychic phenomena, holds out much of promise.

It is our conviction that, with the equipment here described, in the hands of trained instrumenteurs who are also experienced clinicians, the diagnosis and therapy of seminal vesicular conditions will be as precise as they have heretofore been empiric.

THE SEMINAL VESICLES AND THE EJACULATORY DUCTS

HISTOPATHOLOGIC STUDY *

JOSEPH A. HYAMS, M.D.
SAMUEL E. KRAMER, M.D.
AND
JOSEPH F. McCARTHY, M.D.
NEW YORK

This gross and histopathologic study of the seminal vesicles and ejaculatory ducts constitutes one feature of a comprehensive and correlated study of these structures, carried out under the supervision of Dr. Joseph F. McCarthy, director of the Department of Urology at the New York Post-Graduate Hospital. To date, about eighty-four bladders have been subjected post mortem to careful serial microscopic examination of the region between the verumontanum and the interureteric ligament. The sections have been made transversely and sagittally, in such a manner as to include the prostate, ejaculatory ducts and seminal vesicle in their normal relationship to one another. These bladders have been selected from hundreds of necropsies, because of definite gross observations indicating acute, subacute and chronic inflammation of the entire region. An opportunity was thus afforded to study the verumontanum, ejaculatory ducts and seminal vesicles in specimens which presented frank inflammatory lesions of the posterior urethra and upper urinary tract.

Parallel with the microscopic studies of the entire posterior urethral region, gross studies of many hundreds of dissected seminal vesicles were carried out, with special reference to the incidence of gross observations of fibrous perivesiculitis. Cellodin casts of the seminal vesicle, ampulla and ejaculatory duct gave an exact method for determining the varying configuration and gross anatomy of these structures under normal, anomalous and acquired pathologic conditions. The tremendous normal variations in the form, capacity and lumen of the convoluted seminal vesicle tubule, the incidence of sacculations, and the position of the ejaculatory duct in relation to the duct of the seminal vesicle and the terminal portion of the ampulla were thus made amenable to study, making possible observations that are essential for an intelligent understanding of the normal anatomy and physiology of these structures. In the marked normal variation in gross anatomic structure revealed by these studies, numerous configurations and anomalies presented themselves, which were obviously important as predisposing factors for the development of an inflammatory pathologic condition and the subsequent course of such an involvement, once established. Although the minutiae of this study included a great amount of detail requiring separate consideration, information of clinical value was easily extracted from the mass of data possessing only academic interest.

These gross and histopathologic studies were undertaken because the pathology of the seminal vesicles has not received the study it deserves. The normal structure of the ejaculatory duct and the verumontanum has only recently been given adequate study, but the microscopic pathology of these structures has not previously received attention in keeping with the clinical interest and importance of the subject. The application of general pathologic concepts to seminal vesiculitis and inflammation of the ejaculatory duct, although sound in principle, must take cognizance of specific gross and minute anatomic structure peculiar to the region. As applied to the seminal vesicle, the chief pathologic problem is not the marked destructive suppurative involvements of the prostatic and seminal vesicular regions (which clinical experience and pathologic knowledge accept as being productive of marked tissue reaction, with permanent cicatrization at the expense of normal structure) but rather the incidence, type of reaction, chronicity and extent of involvement of these structures during the course of and subsequent to low grade chronic posterior urethritis and adnexitis. Is chronic latent seminal vesiculitis a frequent cause of morbidity? Does chronic infiltrative involvement of the seminal vesicle wall occur frequently with the ordinary forms of prostatitis and seminal vesiculitis? Does marked fibrous perivesiculitis commonly accompany chronic prostatitis and cicatricial posterior urethritis?

What are the types of pathologic response in the ejaculatory ducts, with different degrees and stages of inflammation in the posterior urethra, prostate and seminal vesicles? Does permanent or intermittent obstruction occur commonly either because of fibrous infiltration of the ejaculatory duct walls or because of congestive and edematous swelling?

The answers to these questions entail a knowledge of pathogenesis of the inflammatory involvements of the entire region. Necropsy studies of material demonstrating the different stages, degrees and types of inflammatory response in all the adnexal structures must give a more accurate conception of the entire picture than can be obtained from clinical observation alone. Nevertheless, the ideal mode of approach to the answer of these interesting problems must be by the avenue of careful gross and microscopic study of necropsy material, with an interpretation based on an extensive and profound clinical experience with the types of infection under discussion.

Clinical experience has shown that all the adnexa are closely related in their response to infectious injuries. It has therefore been taken for granted that the ejaculatory ducts must be affected by inflammatory

* Read before the Section on Urology at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 12, 1931.

infiltrations similar to those that are clinically demonstrable in the contiguous structures. The ready inflammatory response of the verumontanum is perhaps the most striking picture in posterior urethroscopy, and this indirect observation, rather than instrumental or microscopic evidences, has led to the general belief that infiltrative and edematous closures of the ejaculatory ducts are not uncommon occurrences.

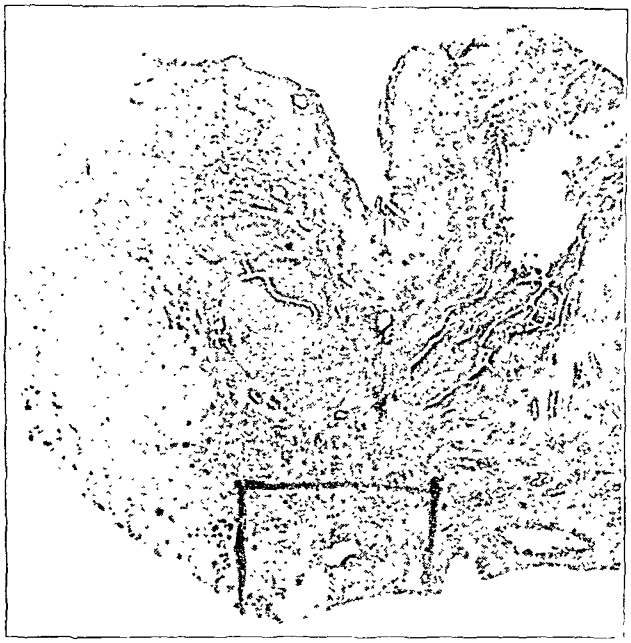

Fig. 1.—Transverse section through the prostatic urethra in a specimen showing prostatic abscess. Marked acute inflammatory reaction throughout the entire prostate, especially marked in the region of the destructive suppurative focus

The gross studies of our specimens revealed very few visual or tactile criteria for the recognition of a chronically inflamed seminal vesicle. Except in a few frank cases of perivesicular infiltration and suppuration, little gross evidence could be found on which to venture an opinion as to the probability of microscopic seminal vesiculitis. The impression of perivesicular infiltration was simulated by varying development of fibro-areolar supporting tissue, which on more careful dissection was found to have no intimate adhesive relation to the seminal vesicle. The gross impression of a thickened, sclerosed seminal vesicle wall was frequently dispelled on subsequent microscopic examination, at which time the vesicular musculature was found to be quite normal, although frequently increased in thickness. The striking difficulty encountered in the recognition of a pathologic seminal vesicle in the gross visual and tactile examination of the specimen serves to emphasize the clinical difficulties in digital rectal diagnosis of chronic seminal vesiculitis.

A marked variation in the thickness of the vesicle wall was noted; in some specimens the wall was very thin, while in others it was so thick that the gross impression was that of sclerosis. It seems noteworthy that in one instance thin distended vesicles were found associated with a frank, atonic, thin, neurogenous bladder (cord injury). However, the impression derived following the microscopic studies was that functional and neurogenous factors, rather than inherent infiltrative lesions of the vesicle wall, caused much of the marked variation in the consistency and thickness of the vesicles examined.

The most reliable gross criteria of the probable presence of chronic seminal vesiculitis were found in the prostatic urethra. Subsequent microscopic study of the seminal vesicle revealed that chronic inflammatory pathologic changes were most frequent in those cases showing frank advanced sclerosis of the posterior urethra and vesical neck, cribriform deformity in the region of the verumontanum, and dilated sclerosed, patent, prostatic ducts, with or without distortions of the size, shape and position of the verumontanum. The size and consistency of the prostate were helpful only as they served to corroborate the impression of widespread chronic inflammation of the entire region, derived from the examination of the mucous surface of the posterior urethra and bladder neck.

In not a single instance did digital pressure on the seminal vesicles fail to cause an escape of secretion through the orifices of the ejaculatory ducts. This was considered ample evidence of the anatomic patency of the ejaculatory ducts. However, it is understood that such a maneuver does not stimulate the physiologic emptying and transmission of secretion from the seminal vesicles to the posterior urethra. It does not preclude the possibility of intermittent occlusion during life occasioned by infiltrative and edematous lesions of the ducts nor does it give any indication as to functional disturbance of the musculature of the seminal vesicles.

From the foregoing it is evident that careful microscopic examination was necessary to determine the presence or absence of pathologic changes in the seminal vesicles and ejaculatory ducts in those specimens in which gross anatomic observations suggested inflammatory involvement of the entire posterior urethral region. Confusion was caused by the microscopic picture resulting from the sectioning of the irregular convoluted and sacculated vesicles as well as its ducts and ampullae of the vas. The villous arrangement of the mucosa of these organs also served to complicate the picture, and in a single section different portions of the vesicles would be cut in different planes resulting in microscopic observations which simulated obliterative changes, growing together of the villi and closed off superficial recesses. Such microscopic criteria have been erroneously described as characteristic of chronic vesiculitis. Because of the frequency of these observations without any other microscopic evidences of inflammation, it

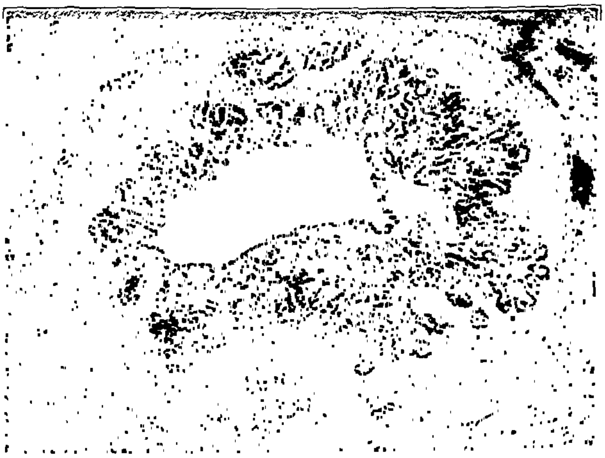

Fig. 2.—Higher magnification in the region of the ejaculatory duct (of figure 1), showing marked engorgement of the blood vessels in the wall, with large perivascular accumulations of polymorphonuclear leukocytes and plasma cells. Similar cellular exudation in the submucosa and between the mucous folds in the lumen.

was concluded that more definite criteria were necessary in order to decide that a vesicle was pathologic. The presence of polymorphonuclear, plasma or round cells in the lumen, between the mucous folds and in the submucosa, with perivascular round cell infiltration about newly formed and engorged blood vessels in the submucosa, muscularis and surrounding fascial planes, was considered necessary to establish a microscopic diagnosis of vesiculitis. Increase in fibrous tissue and variation in elastic tissue were determined by the use of differential stains.

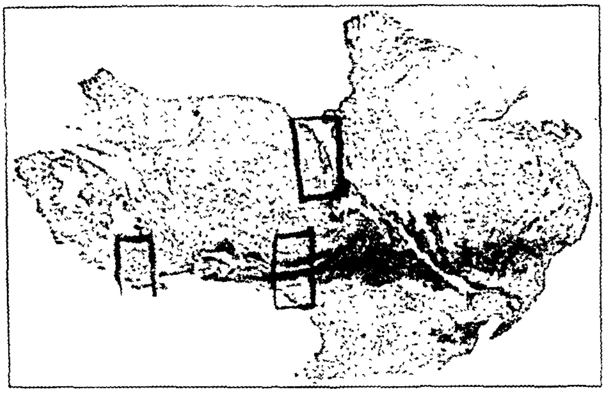

Fig. 3.—Large sagittal section showing active subacute inflammation of the posterior urethra, prostate, ejaculatory duct and seminal vesicle.

Because of their intimate anatomic and functional relationship the pathologic changes of the seminal vesicles, ejaculatory ducts, utricle and verumontanum must be considered together. Since the ejaculatory ducts course through the prostate, the pathologic changes in the latter organ cannot be ignored when one is considering the morbid changes in the former.

By far the most common form of seminal vesiculitis is produced by regional extension following posterior urethritis. Infection of the blood stream is possible, as is secondary involvement from a focus in the epididymis (tuberculosis). However, the most common form is the result of direct extension complicating infection of the posterior urethral surface. Regional extension occurs by continuity of the mucosal surface, as well as by means of lymphatic invasion. In relatively mild posterior urethritis of gonorrheal or nongonorrheal etiology, the juxta-urethral structures alone are involved. In more virulent or constantly repeated mild infection of the posterior urethra, regional extension occurs to the more remote points in the adnexal structures. Minute anatomic structure plays an important part in determining the chronicity and type of tissue reaction.

It is therefore obvious that infection of the prostate glands usually occurs concomitantly with infection of the ejaculatory ducts and the accessory gland structures. In mild inflammations, the involvement may be juxta-urethral both in the prostatic and in the seminal tracts. In more virulent infections, the inflammatory processes in the deeper recesses of the prostate and seminal vesicles cannot fail to be accompanied by similar involvement of the juxta-urethral structures. As applied to the seminal vesicle and ejaculatory duct, our studies showed that seminal vesiculitis of any severity was never seen without definite, marked inflammation of the ejaculatory duct. However, not infrequently, mild chronic surface urethral inflammation with low grade chronic prostatitis and inflammation of the glands of the verumontanum and terminal portion of the ejaculatory ducts was found with practically no microscopic evidences of seminal vesiculitis.

The material that was studied fell into the following groups:

1. Specimens which showed active gross suppurative lesions of the prostate and the periprostatic and vesicular regions.
2. Specimens which showed gross manifestations of active, acute or subacute inflammation of the urethra and the bladder neck, with indefinite gross evidences of prostatic or seminal vesicular inflammation.
3. Specimens which showed cicatricial changes of the vesical neck and posterior urethra, with patent dilated prostatic ducts, cribriform deformity of the prostatic urethra and distortion of the verumontanum. Gross evidences of vesicular induration and infiltration were indefinite and difficult to interpret.
4. Specimens which showed little change in the posterior urethra, with chronic inflammatory lesions of the upper urinary tract.

In the first group showing gross suppuration of the prostate and the periprostatic and vesicular regions, the microscopic picture was very striking. The mucosa and submucosa of the posterior urethra and vesical neck showed very marked exudative infiltration with polymorphonuclear leukocytes and plasma cells. The prostate showed marked intra-acinous and periacinous cellular exudation. Several large destructive suppurative foci were found, surrounded by areas of young fibrous tissue containing many newly formed blood vessels with marked perivascular cellular accumulations (fig. 1). Within the lumen of the ejaculatory ducts. pus, plasma and desquamated epithelial cells were found, and their walls in the prostatic portion showed definite perivascular infiltration about numerous engorged blood vessels (fig. 2). Destructive suppurative involvement of the prostate was not sufficiently close to give more marked infiltrative involvement of the ejaculatory duct walls.

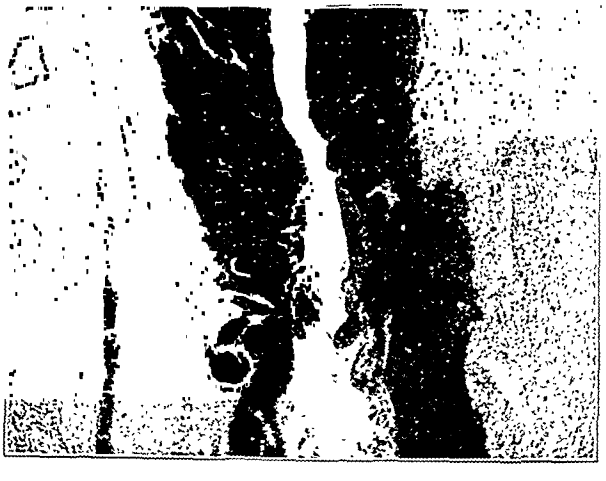

Fig. 4.—A higher magnification through the midportion of the ejaculatory duct shown in figure 3, showing marked submucosal infiltration with polymorphonuclear leukocytes and plasma cells. Blood vessels in the wall are engorged with marked perivascular infiltration. The lumen contains exfoliated epithelium and inflammatory cellular exudate.

The seminal vesicles in this group showed high grade perivesicular and vesicular infiltration by polymorphonuclear leukocytes and plasma cells, with marked perivascular cellular exudation about numerous vessels in the perivesicular tissues and muscularis. The lumen showed numerous desquamated epithelial cells mixed with many pus and plasma cells. Submucosal cellular infiltration was present but not so definite.

In the second group showing active acute or subacute inflammation of the urethra and the bladder neck, with indefinite gross evidences of prostatic or seminal vesicular inflammation, the following microscopic pictures were presented: The submucosa of the entire posterior urethra was densely infiltrated with inflammatory cellular exudate (fig. 3). Marked intra-acinous and periacinous cellular exudation was noted throughout the prostate, associated with perivascular round cell accumulations in the stroma. The verumontanum showed similar changes in its submucosa and glandular elements. The ejaculatory duct revealed marked cellular infiltration of the submucosa and muscle wall with exudation of polymorphonuclear leukocytes and plasma cells into its lumen (fig. 4). The seminal vesicle displayed corresponding inflammatory involvement of the lumen, mucosa and submucosa with less marked infiltrative changes in the vesicle muscularis. The picture presented was typically that of adnexal complication of posterior urethritis occurring by surface extension and without destructive suppurative involvement of any of the structures.

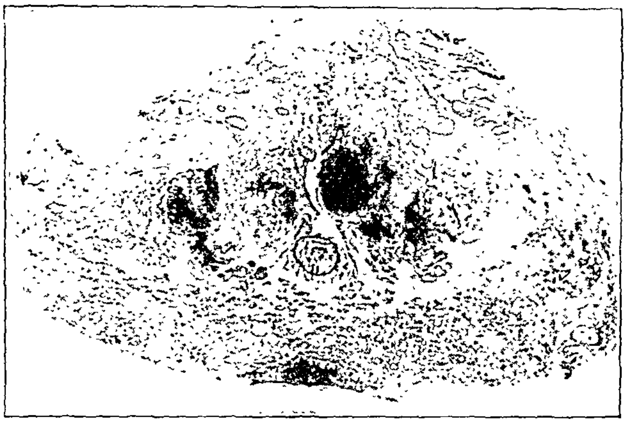

Fig. 5.—Large transverse section (low magnification) through the region of the verumontanum in a specimen demonstrating low grade chronic posterior urethritis and prostatitis. *Note fibroma of the urethral wall encroaching into the lumen.*

In the third group, numerous specimens were studied which showed cicatricial changes of the vesical neck and posterior urethra, occasionally with cribriform deformity, dilated patent prostatic ducts and distortion of the verumontanum. In these specimens the diagnosis of prostatitis was practically always verified on microscopic examination. A limited but definite proportion showed chronic inflammatory changes in some portion of the ejaculatory duct. In the less marked cases usually accompanied by mild chronic posterior urethral inflammation and low grade prostatitis the changes were frequently limited to the juxta-urethral portion of the ejaculatory duct (fig. 5). These changes consisted of engorgement of blood vessels with perivascular round cell infiltration, moderate diffuse periacinous and intra-acinous cellular exudation of the glands of the verumontanum (fig. 6). Desquamation of the epithelium of the ejaculatory duct with slight submucosal fibrous thickening was also seen. These changes became less marked as the seminal vesicle was approached, which frequently showed no infiltration of the wall and scarcely any mucosal or submucosal change.

In the more marked cases, fibrotic changes were found in the submucosa of the urethra and vesical neck. The verumontanum in these specimens showed definite acinous distortion and cystic dilatation with intraglandular and periglandular round cell infiltration. Increased congestion, perivascular round cell accumulations and deposition of fibrous tissue were noted in this structure. The ejaculatory duct in its juxta-urethral portion often showed numerous blood vessels in the wall, round cell infiltration and newly formed fibrous tissue (figs. 7 and 8). Desquamation of the epithelium with fibrous thickening of the submucosa was also noted in this structure. The duct of the seminal vesicle sometimes showed numerous engorged blood vessels with a slight amount of perivascular round cell infiltration. Elsewhere the vesicle wall displayed little evidence of chronic infiltrative inflammation. In some cases numerous round cells, plasma cells and exfoliated epithelium filled the lumen and recesses between the mucosal folds of the seminal vesicle, always with similar exudative products in the lumen of the ejaculatory ducts (fig. 9).

In several specimens with inflammation of the upper urinary tract, low grade inflammatory changes were found in the submucosa of the urethra and in the verumontanum. The ejaculatory ducts were but slightly changed and the vesicles not at all.

COMMENT

Of the eighty-four selected specimens, sixty-six showed microscopic evidence of prostatitis, sixty-two cases being chronic and four acute or subacute; concomitant microscopic changes were found in the posterior vesical neck region in all but two, corresponding in stage and degree with the conditions in the adjacent prostate. Of the sixty-six specimens showing microscopic prostatitis, forty-nine showed a greater or a lesser degree of inflammation of the ejaculatory ducts. Of the forty-nine specimens showing inflammation of the ejaculatory duct, three were found with no seminal vesiculitis, thirty with slight indefinite chronic catarrhal seminal vesiculitis, and sixteen with marked chronic,

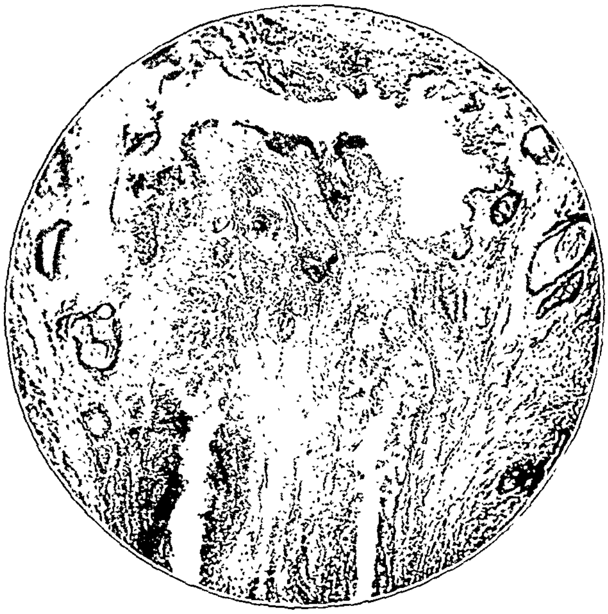

Fig. 6.—Higher magnification of verumontanum seen in figure 5. Submucosal round cell infiltration of ejaculatory ducts and utricle, with similar infiltration about the glands and vessels, indicates low grade inflammatory involvement of this region. The prostate shows low grade chronic inflammation, while the deeper portion of the ejaculatory ducts and seminal vesicles does not show any change.

subacute and acute seminal vesiculitis. Of the sixteen specimens showing marked seminal vesiculitis, only four showed definite inflammatory infiltration of the seminal vesicle wall, one presenting prostatic abscess, one periprostatic abscess, and two marked chronic catarrhal seminal vesiculitis; three specimens demonstrated microscopic evidence of perivesiculitis, one presenting chronic catarrhal seminal vesiculitis and two subacute purulent vesiculitis with prostatic and periprostatic abscess. No marked seminal vesiculitis was seen without corresponding inflammation of the ejaculatory duct.

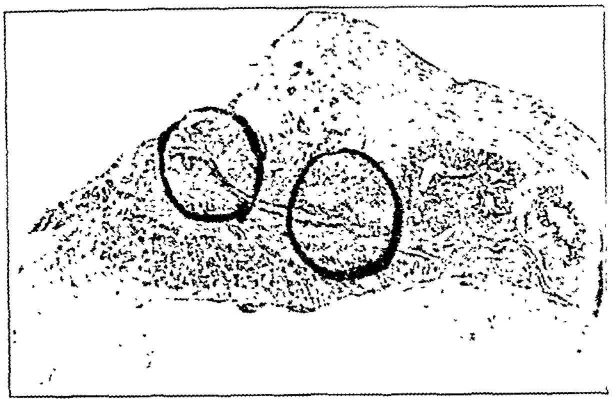

Fig. 7.—Large sagittal section of the posterior urethra and vesical neck floor in a specimen displaying chronic prostatitis and inflammation of the verumontanum, ejaculatory duct and seminal vesicle.

On the basis of the microscopic studies made, it is possible to state definitely that inflammatory infiltrations occur in the walls of the seminal vesicles and ejaculatory ducts. It is also obvious that intermittent congestive obstruction of the latter must occur in a manner similar to that found in other epithelial-lined ducts with pathologically narrowed lumens. The lumen can easily become occluded temporarily by inflammatory débris arising in the seminal vesicle or in the ejaculatory duct itself.

Although the foregoing conclusions can be made, our studies do not show that such chronic infiltrative changes occur frequently in the muscularis of the seminal vesicles. Only in the presence of active, destructive, suppurative adnexal inflammation was marked perivesicular inflammation found. Such cases showed corresponding changes in the wall of the vesicle, and the lumen participated in the active surface inflammation in the urethra and ejaculatory ducts. The changes were sufficient to interfere with normal functional activity. Similarly, the ejaculatory ducts, in these cases, showed sufficient active infiltrative inflammation to permit of intermittent obstruction, either because of congestive changes or because of occlusion by inflammatory débris. Permanent occlusion of the ducts, due to subsequent scarring, seemed to be a remote possibility.

However, studies of the rather frequent ordinary forms of chronic posterior urethritis led to the conclusion that the aforementioned reaction is quite exceptional.

In the great preponderance of cases in which inflammatory changes were found in the seminal vesicles, associated with gross observations of posterior urethral and vesical neck cicatrization and low grade prostatitis, the microscopic picture was entirely different. Marked changes in the vesicle wall and perivesicular region were usually absent, and superficial changes alone were noted in the submucosa, mucosa and lumen. When definite superficial inflammation was noted in the vesicles, without infiltration of the wall, corresponding superficial changes were noted in the ejaculatory ducts in all the specimens. In a limited number of these cases mild inflammatory changes were noted in the ejaculatory duct walls, consisting of round cell infiltration and in a few instances scar formation. In some specimens the juxta-urethral portion of the ejaculatory duct showed chronic inflammatory infiltration diminishing in severity as the seminal vesicle, which was apparently normal, was approached.

It seems probable that the ordinary mild forms of seminal vesiculitis, occurring by surface and lymphatic extension, fail to involve the vesicle wall with any marked infiltrative reaction. Similar to that of any epithelial-lined organ, in the absence of glandular invaginations, the inflammatory reaction tends to remain superficial or catarrhal in nature. The poor drainage afforded the vesicles by the narrowed ejaculatory ducts and the folded arrangement of the mucosa are factors which tend to produce chronicity. But even under these circumstances the muscle walls seem to be subjected to little injury in most instances.

The ejaculatory ducts, on the other hand, are subjected to different influences. Being situated close to the urethra and being intimately surrounded by a gland which is very prone to chronic infection, the ejaculatory duct should show a higher rate of deep seated cicatrization and round cell infiltration than would the seminal vesicles. In addition, the terminal juxta-urethral portion is intimately related with glandular structures, some of which communicate with the duct directly. The verumontanum from its situation and structure frequently undergoes marked inflammatory change, and it is evident that the terminal portion of the ejaculatory duct must be more susceptible to infiltrative changes in this region. Our studies have demonstrated this to be true. In many instances, chronic ejaculatory duct inflammation was found without corresponding changes in the deeper coats of the vesicles. The arrangement of blood vessels in the verumontanum and in the ejaculatory ducts demonstrates the ability of these structures to become engorged. Irritative congestion superimposed on infiltrative lesions, which in themselves may

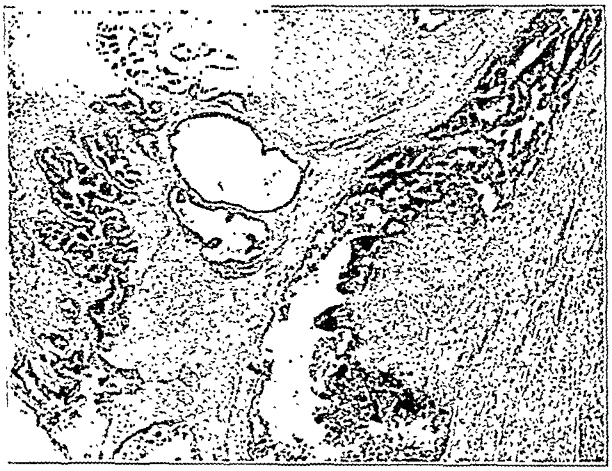

Fig. 8.—High magnification of the ejaculatory duct in the region of the verumontanum shown in figure 7. Chronically inflamed cystic glands, intra-acinous and periacinous cellular exudation as well as perivascular round cell infiltration are noted. The stroma adjacent to the ejaculatory duct shows numerous blood vessels with perivascular round cells and an increase in newly formed fibrous tissue. The mucosa and submucosa show round cell infiltration with desquamation of epithelial cells, round cells and plasma cells in the lumen.

not be obstructive, can produce intermittent occlusion of the lumen of the duct.

Our studies make it evident to us that the ejaculatory ducts are always involved in posterior urethral inflammation. In the greater number the infection is mild and juxta-urethral, and of these only a relatively small percentage cause sufficient involvement to eventuate in chronic infiltrative changes of the terminal portion of the duct. In cases in which, because of various factors, infection of the adnexa becomes more widespread and chronic, catarrhal inflammation of the ejaculatory ducts and seminal vesicles will be found in conjunction with a diffuse follicular prostatitis. In a definite proportion of these cases chronic inflammatory changes of the wall of the juxta-urethral portion of the ejaculatory duct (associated with productive inflammation of the verumontanum) will occur eventually, with diminishing tendency toward such involvement as the seminal vesicles are approached.

The seminal vesicles, in the greatest number of chronic adnexal inflammations, show superficial inflammatory changes of a chronic type, with little evidence of infiltration of the walls. This pathologic observation should not be interpreted to mean that chronic seminal vesicular infection is uncommon but merely that marked inflammatory response in the wall and perivesicular tissue does not occur with the ordinary types of chronic vesiculitis. Such marked involvement is seen only in conjunction with overwhelming regional inflammation of the destructive suppurative type.

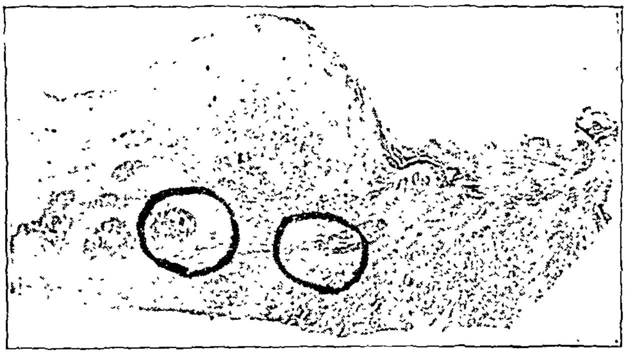

Fig. 9.—Sagittal section through the posterior aspect of the entire vesical neck and posterior urethral region. A case showing chronic posterior urethritis, prostatitis, seminal vesiculitis and inflammation of the ejaculatory duct.

Clinical experience accepts the conception that spread of infection from the posterior urethra occurs by way of mucosal continuity and lymphatic invasion. The lymphatics of the posterior urethra are known to drain with those of the prostate and seminal vesicle to the hypogastric and external iliac glands. Active infection and inflammation of these structures may result in acute lymphangitis and regional lymphadenitis, with or without local inflammatory infiltration of the affected region. With the subsidence of the focal infection, lymphangitis becomes less marked, although the lymph nodes remain enlarged for a considerable period. Numerous specimens are noted of frank cicatricial posterior urethritis and chronic quiescent prostatitis, with or without inflammation of the ejaculatory ducts and the seminal vesicles, in which the regional lymph nodes were enlarged but with no perivesicular fibrosis. It is conceded that these necropsy observations do not preclude the possibility of the previous incidence of temporary infiltration and inflammatory thickening of the periprostatic and perivesicular regions, with complete or almost complete absorption of exudate and a return to normal with a minimum degree of postinflammatory fibrosis. Here again the rich lymphatic and blood supply, which would seem to predispose to regional spread to the perivesicular regions, with the deposition of chronic inflammatory exudate may really promote rapid absorption of inflammatory products in this region.

On the other hand, marked destructive suppurative involvement of the prostate and seminal vesicles causes marked exudative response of the entire region, and with marked suppurative destruction of tissue, reparative processes should result in fibrosis of the vesicles and perivesicular regions. Even in such cases absorption of a great proportion of the inflammatory mass occurs. These considerations may explain the fact that necropsy studies fail to encounter vesiculitis and perivesiculitis with the same frequency that would be expected from clinical impressions alone.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. MC CARTHY AND RITTER AND DRS. HYAMS, KRAMER AND MC CARTHY

Dr. J. Sydney Ritter, New York: I will show a slide which emphasizes the fact that one cannot have pathologic changes in the prostate without some changes in the ejaculatory ducts. One slide demonstrates a condition which I think Drs. Hyams, Kramer and McCarthy failed to mention; that is, infection involving the utricle. Now that pathologic changes are known to exist in the seminal vesicles and ejaculatory ducts, the question of therapy arises. What is one going to do to effect a cure? Some time ago seminal vesiculectomy was advocated, and many have attempted it, with such poor results that it has practically disappeared from therapeutic surgical procedure. I think this is largely due to the fact that the diagnosis has been based on a rectal examination with the uncertain finger and on the more uncertain subjective symptoms of the patient. These results are due to the fact that no attention is paid to the ejaculatory ducts, and drainage through them is not favored. Vasotomy is objected to because that means a surgical procedure with no attention paid to the ejaculatory duct. The procedure advocated today by Drs. McCarthy and Ritter should *be a universal practice because vesiculitis can be diagnosed* scientifically. One should note the condition of the ejaculatory duct, medicate the vas deferens, dilate the duct and pave the way for cure.

Dr. A. E. Bothe, Philadelphia: One needs only to have worked with desiccated seminal vesicle specimens to know what difficulties Drs. Hyams, Kramer and McCarthy must have encountered in collecting the interesting group shown in the scientific exhibit. Dr. Coulbeck and I have been working along the same lines, and although we have not studied as many specimens, we have done enough to realize the difficulties that one encounters in this work. It is the anatomic relation of the vasa deferentia, the ducts of the seminal vesicles and the ejaculatory ducts to which I wish to make especial reference. Before preparing our specimens for desiccation, we injected sodium iodide through the vasa deferentia and took roentgenograms. These pictures consistently showed that the ejaculatory duct is a continuation of the duct of the seminal vesicle. They also showed that the vasa deferentia joined the seminal vesicle duct at various angles, ranging from the extreme acute type up to an almost complete right angle. The desiccated specimens also gave evidence of this relation. In another group of specimens we made a number of serial sections through the region of the ducts. These showed definitely that the seminal vesicle ducts are larger than the vasa deferentia and that the latter join the duct of the seminal vesicle, which becomes the ejaculatory duct. If one considers this anatomic relation of the ducts of the seminal vesicle, vasa deferentia and ejaculatory ducts, it is easy to see the marked influence which periductal inflammatory changes may have in causing obstruction which may play an important part in sterility, as well as other symptoms.

Dr. J. Dellinger Barney, Boston: Fifteen or eighteen years ago, when many seminal vesicles were being taken out because of disease, I injected many of them, and the roentgenogram showed almost the identical pictures that Drs. McCarthy and Ritter have so well demonstrated. After a good deal of experience I got so that I could tell before taking out the seminal vesicle whether it was or was not the seat of disease. It showed the changes in the lumen and in the conformation. I also verified the work of Picker many years ago, in which he was able to divide the contour of the seminal vesicle into three or four portions. I think that with some experiences one can tell whether the seminal vesicle is or is not diseased before taking it out. I wish to know how far into the ejaculatory duct one can pass the catheter.

Dr. J. A. Hyams, New York: Because of the brief time allotted, we were able to discuss only eighty-four specimens. In the study of celloidin casts, demonstrated in detail in the exhibit, an additional forty series of microscopic sections of the uninjected opposite seminal vesicle were examined. Although these sections corresponded in part as to histopathologic observations, the amount of pathologic change was greater in the larger sections, emphasizing the importance of large sagittal and transverse sections through the seminal vesicles and contiguous structures. Picker injected seminal vesicles with bismuth paste, took roentgenograms and dissected the vesicular mass. He demonstrated the structure of the seminal vesicle. Pallin made casts to study the embryologic structure, but his technic was not available. Such work does not suffice for our present needs. Therefore, not only casts but roentgenograms, microscopic examination of the secretion, and complete gross and histopathologic studies were made in order to determine the pathologic changes present in these structures. Histologic investigation of isolated structures falls short of the desired result, and only by complete pathologic studies such as we have made, combined with parallel clinical and instrumental observations as presented by Drs. McCarthy and Ritter today, can a proper conception of the pathologic changes be derived. Impressions of abnormality in the seminal vesicles as shown by digital palpation or ordinary methods of examination are necessarily incomplete. The complexity of the vesicular mass is such that no two vesicles can be said to be the same. Variations occur on the two sides in the same individual. Furthermore, a fairly definite relationship has been found to exist between inflammatory change at the posterior urethra, vesical neck and adnexa. Vesiculitis presupposes urethral involvement. With increasing complexity of the seminal vesicle there is greater incidence of infection, and drainage becomes more difficult. Evacuation of secretion is further impeded by superimposition of abnormalities. The persistence of infection is dependent on the complexity of the structures rather than on the type of virulence of the infecting agent. In our dissection of 500 bodies, perivesiculitis and terminal fibrosis was found in only six cases. Thorough methods of clinical investigation by those individuals who by their training and experience are particularly well qualified in this field, coordinated with more extensive studies along broad pathologic lines, will eventually lead to greater diagnostic accuracy and improved methods of treatment of diseases of these structures.

Dr. J. F. McCarthy, New York: Emphasis is laid on the proximity of the two ducts, to call attention to the great care that must be exercised in these injections. The ducts are separated by so thin a membrane that it is possible to inject on one side and find a vesiculogram of the other. The paper contains all the material that we did not have time to elaborate. Dr. Barney has asked how far the catheter may be introduced. From 2 to 2.5 cm. is sufficient.

The Background of Personality.—The most fundamental characteristic of normal human personality is unity, wholeness, integration. This integration appears in many ways. It is shown in the tropisms of plants and animals and in concentration of attention to the child and the adult. The general function of the nervous system is integration. Recent studies of the brain put emphasis also on the whole rather than any special part.—Burnham, W. H.: The Wholesome Personality, New York, D. Appleton & Co., 1932.

THE RELATION OF CONGENITAL DEFORMITIES OF THE HAND TO CERVICAL RIBS *

ROBERT V. FUNSTON, M.D.

DETROIT

Several months ago a woman, aged 50, and her daughter, aged 9, were examined in the orthopedic clinic at Harper Hospital. The mother had a bilateral absence of the radius with club hand deformity and rudimentary thumbs. The daughter had an exactly similar deformity of the right hand. The left hand of the daughter, however, had no thumb and there was a synosteosis between the radius and the ulna just distal to the elbow joint.

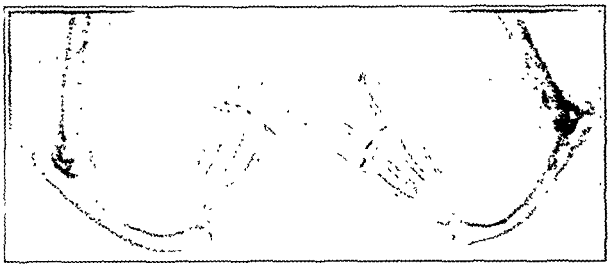

Fig. 1 (case 1).—Right and left hands, showing rudimentary radii.

During the examination, cervical ribs were palpated in the neck of the mother, and roentgenograms revealed well developed cervical ribs in both mother and daughter, as shown in figure 2.

The finding was so striking that two patients with club hand previously seen were brought back for roentgen examination, and both were found to have cervical ribs.

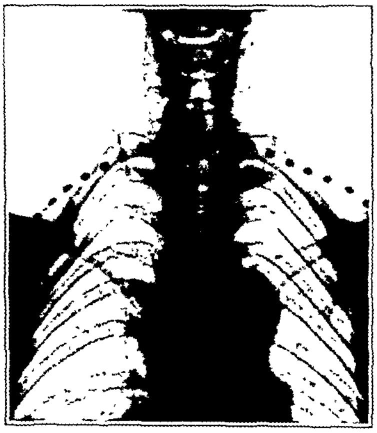

Fig. 2 (case 1).—Cervical spine showing large hornlike cervical ribs.

A baby about 3 months old was recently seen for the first time in the clinic and showed also the presence of cervical ribs.

Whether the presence of cervical ribs in congenital absence of the radius in these five cases is coincidental or a consistent finding, I am anxious to determine.

In no instance in this series was there a complete absence of the radius, but in five instances in the six club hands present there was only a small proximal portion of the radius to be seen. In the other case, the radius, although rudimentary, articulated with the carpal bones.

In reviewing the literature on the subject, including textbooks, I do not find mention of any association of the two deformities.

Pasquali,[1] in 1880, reported a typical case of bilateral absence of the radius in a child. There was, in addition, absence of both first metacarpal bones and of certain carpal bones. The thumbs consisted of two phalanges and were attached to the hand by a minute cutaneous peduncle. The hands, which were articulated directly with the ulna, were found in a position of such marked adduction that the external edge of the hand formed an approximate right angle with the corresponding margin of the forearm. The four fingers of the hand showed clinodactyly with moderate flexion deformity.

[1] Pasquali: Un bambino mancante di ambedue le ossa del radio (Case of Bilateral Absence of the Radius in a Child), Boll. d. Accad. med. di Roma 6: 6, 1880.

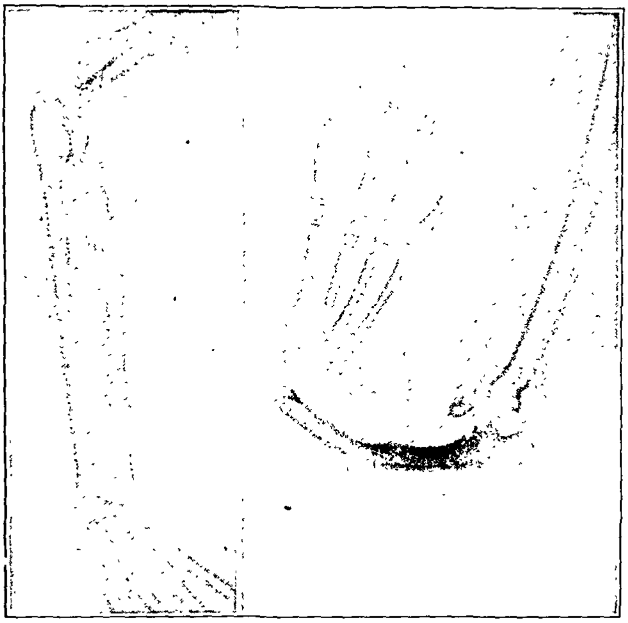

Fig. 3 (case 2).—Right and left forearm, showing on the left rudimentary radius with club hand; on the right, synosteosis between radius and ulna in the upper third.

Cuff,[2] in 1896, reported an interesting case of the absence of the radii in both arms which developed after the age of 17, as a result of congenital syphilis. Congenital syphilis has been mentioned in several instances as a possible predisposing cause of the deformity.

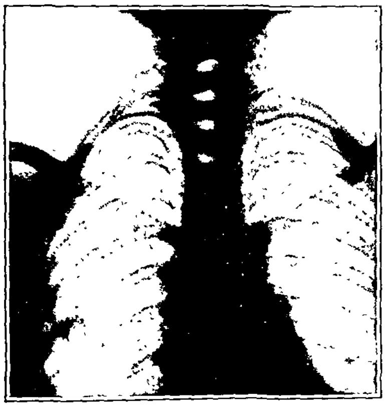

Fig. 4 (case 2).—Cervical spine, showing large cervical ribs.

Reisz,[3] in 1904, presented a typical case of bilateral congenital absence of the radius in a woman, aged 20.

Illyes,[4] in 1907, presented a case in an infant.

Roschke,[5] in 1912, drew attention to the fact that the upper arm and scapular regions appeared normal in a case presented by him. He described in detail the muscular action exhibited in the use of the hands.

Garrido Lestache,[6] in 1918, presented a typical case of "radiopalmar club hand" in an infant, aged 9 days.

Infante[7] draws attention to the fact that in his patient, a little girl, there was no involvement of any other part of the body.

Oidtmann[8] presented a case of a boy, aged 7 months, on whom he operated, bifurcating the lower end of the ulna and attaching the scarified carpus into its normal position. Roentgenograms taken several months later showed that the bifurcated extremities of the ulna had thickened and enclosed the carpus.

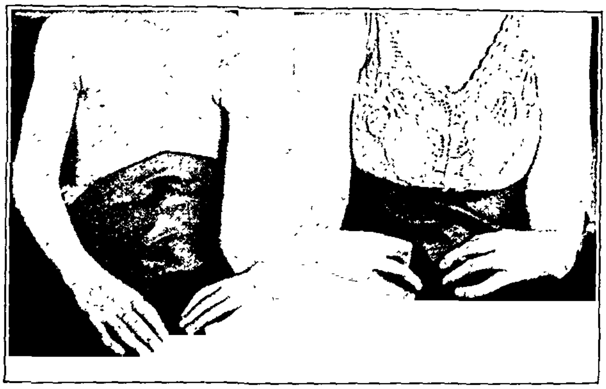

Fig. 5 (cases 1 and 2).—Mother and daughter, showing typical deformities.

Spears,[9] describes a child, aged 20 months, showing "considerable shortening of both forearms with adduction of both wrists, giving the hands the appearance of feet." He applied plaster of paris to correct the deformity.

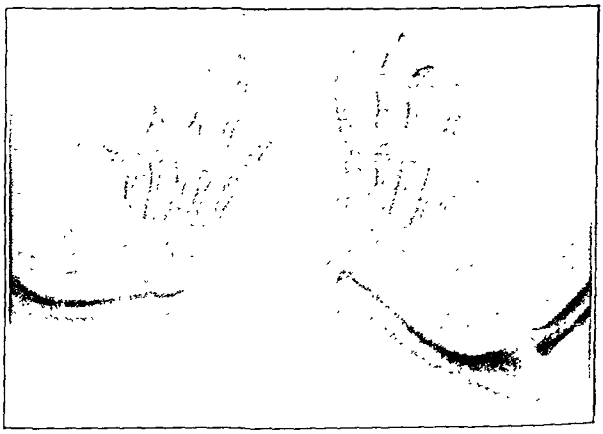

Fig. 6 (case 3).—Club hand with rudimentary radii and first metacarpals.

Alonzo,[10] in 1925, reports three cases of congenital deformity of the forearm in adults, in which the radius was absent in two cases; the ulna, in one instance. He states that among 1,444 cases of deformity, Hoffa noted the absence of the radius in one, while Dollinger did not note it once among 859 cases. In Raboud and Hovelacque's statistics, in 1924, absence of the fibula was noted in 268 cases, of the tibia in 122 cases, of the radius in 220 cases, and of the ulna in 71 cases. Ratsuji Kato's statistics included 253 cases of a defective radius. Amniotic constriction, intra-uterine fractures, ischemic phenomena and mental injury of the mother are considered, among others, as etiologic factors. In Alonzo's opinion, endocrine disturbances, especially of the pituitary, are responsible for congenital hemimelia.

Lewin,[11] in 1918, and Gaenslen,[12] in 1914, both presented a series of cases, but neither reported any abnormalities in the cervical spine.

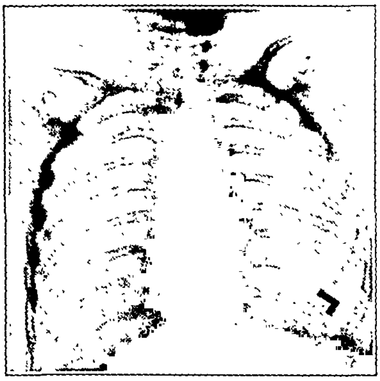

Fig. 7 (case 3).—Cervical spine showing cervical ribs.

The cases that are being presented in this paper are typical, except that in one case the radius was not as rudimentary as in the others. In all the cases, the thumb was rudimentary and was attached only by a cutaneous peduncle.

The presence of the condition in a mother and daughter strongly favors an hereditary basis. In no instance was there any history of syphilis and in all instances the Wassermann reaction was negative.

One striking fact was noted: that the difference in development of the arm, as far as length was concerned, in a comparison of the mother and daughter in this series, was very slight. The length of the ulna as developed in the mother was 5½ inches (14 cm.). As developed in the daughter at the age of 9, 4½ inches (11.5 cm.). This fact makes it seem an advantage to correct surgically the deformity in these cases early, so as to obtain the maximum muscular development and dexterity of the hand, rather than to wait for the osseous growth.

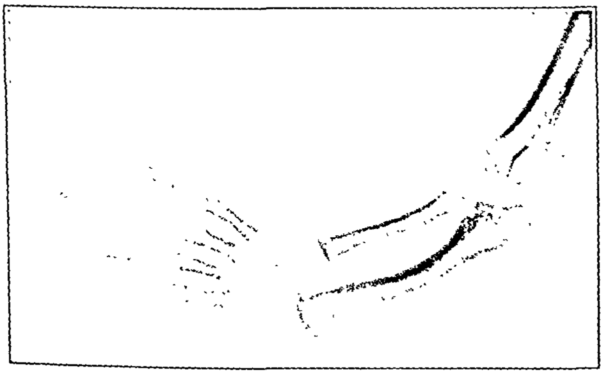

Fig. 8 (case 4).—Rudimentary radius and thumb.

Three of the patients herein mentioned have received treatment. The patient who had a complete but undeveloped radius was operated on, and a portion of the ulna was removed in the middle third. The deformity was then corrected and has remained so. The rudimentary thumb was amputated and a thumb was devised from the index finger by making a cleft between the metacarpals and rotating the finger by osteotomy. A resection of the distal interphalangeal joint, with removal of part of the middle phalanx later, improved stability. The end-result was a satisfactory three fingered hand with a thumb, which functioned almost normally.

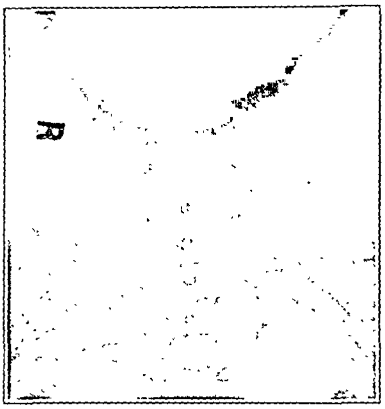

Fig. 9 (case 4).—Cervical spine showing cervical ribs.

The operation performed in the second case was the correction of the deformity and arthrodesis of the ulna to the carpus. This was done by Dr. Frank Curtis at the Children's Hospital and resulted in marked improvement in the function of the hand.

The third patient, a baby seen a few weeks after birth, was treated by a plaster-of-paris dressing until overcorrection was obtained. A splint was then applied to maintain correction until sufficient growth had occurred to justify operative procedure.

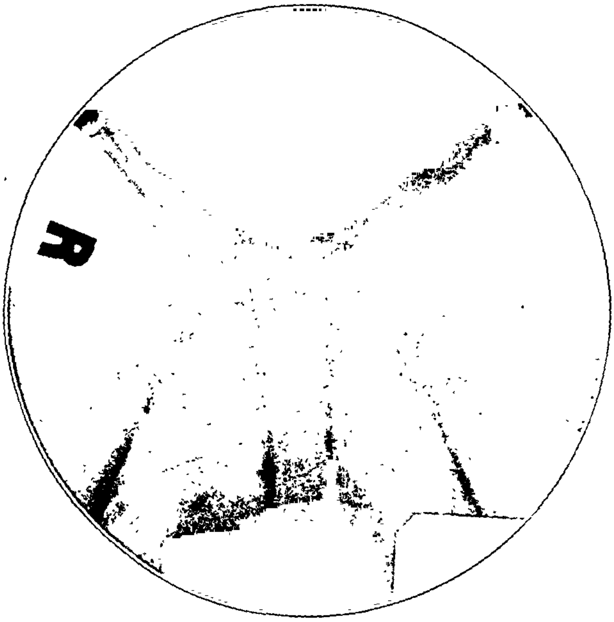

Fig. 10 (case 5).—Cervical spine showing cervical ribs.

The mother and the daughter refuse treatment.

Two additional cases have been added to this series by Drs. Robert Schrock of Omaha and F. J. Gaenslen of Milwaukee, showing club hand deformities and cervical ribs.

ABSTRACT OF DISCUSSION

Dr. Philip Lewin, Chicago: In a series of cases reported in 1918 I failed to have roentgenograms taken of the cervical spine. *I shall* try to get some of the patients to come back for that examination. Dr. Funston is emphasizing the importance of this seventh cervical region and some day the proper importance will be attached to it. It took many years for the fifth lumbar vertebra to obtain its due recognition. I should like to ask Dr. Funston at what age he expects cervical ribs to show. I reported one instance of cervical rib in a case of brachial birth palsy, associated with osteochondritis of the upper end of the humerus in a girl aged 6 years.

Dr. F. J. Gaenslen, Milwaukee: The observation of the peculiar broadening of the neck of the mother of one of the patients apparently led to the search and to the finding of further cases in which congenital deformities of the hand and cervical rib were associated. The fact that five or six such cases were found would seem to indicate that this was not a coincidence. I had hoped that Dr. Funston would set up a hypothesis for us to shoot at, as it seems easier in this case to disagree with any of the theories suggesting themselves than it is to offer one that will stand scrutiny. I certainly have none to offer.

Dr. Robert V. Funston, Detroit: In answer to Dr. Lewin's question, the earliest case was in a child aged 8 weeks when the roentgenogram was taken. The cervical ribs did not show up clearly. They do not show up so clearly in the younger children as they do later on. I should like to say also that Dr. Schrock of Omaha sent me a photograph and roentgenogram of a child whom he saw, and the child showed a definite cervical rib. Dr. Gaenslen also has reported a case. The child was very young. The roentgenograms seem to show a cervical rib, but I wouldn't be willing to say, as they are not very clear.

IMMEDIATE CECOSTOMY AND CONSTANT LAVAGE IN MERCURIC CHLORIDE POISONING *

S. S. BERGER, M.D.
H. S. APPLEBAUM, M.D.
AND
A. M. YOUNG, M.D.
CLEVELAND

An analysis of 163 cases of mercuric chloride poisoning in the Mount Sinai Hospital of Cleveland, both from the clinical and particularly from the pathologic point of view, has demonstrated the importance of gangrenous colitis in the course of mercury poisoning.

It has been the general conception in the past that most patients with mercury poisoning die of renal insufficiency. "Unless a fatal issue results early from shock or some other unusual occurrence, the patient [poisoned by mercury] virtually lives or dies by his kidneys." [1]

In the past five years, the number of patients (seventeen) with mercury poisoning coming to autopsy at Mount Sinai Hospital of Cleveland were found to fall into three groups (table 1): Group 1. Those dying within forty-eight hours of the ingestion of the poison in shock, following an extensive and severe gastritis, with marked hemorrhagic necrosis of the stomach wall. Group 2. Those dying from forty-eight hours to seven days after the ingestion with retention of nitrogenous substances following a severe necrotizing nephrosis. Group 3. Those dying from seven to twelve days after ingestion with an extensive and severe gengrenous *colitis, the kidney lesion at this* time showing evidence of healing.

The colonic lesion, therefore, is one of the three most important causes of death in mercuric chloride poisoning.[2] *Therefore, measures to combat this* serious involvement must of necessity assume an important rôle in the treatment of mercuric chloride poisoning, and we have found immediate cecostomy and constant colonic lavage to be the most effective.

Table 1.—*Lesions of Mercury Poisoning*

	Duration		
	Within 24 Hours of Ingestion	From 48 Hours to 7 Days After Ingestion	From 7 to 12 Days After Ingestion
Number of cases	6	7	4
Principal lesion	Extensive severe gastritis (fig. 1)	Necrotizing nephrosis (figs. 2, 3 and 4)	Extensive, severe gangrenous colitis (fig. 5)
Other lesions	Shock; alteration of blood with increased fluidity and inability to clot	Retention of nitrogenous substances; generalized parenchymatous degeneration; gastritis of variable severity	Gangrenous stomatitis; healing nephrosis; healing gastritis

The idea of cecostomy is not new. Perhaps the first to try cecostomy early in mercury poisoning was Anderson, who in 1915 reported recovery of a girl, aged 19 years, in whom cecostomy was done about fourteen hours after the ingestion of 10 grains (0.65 Gm.) of mercuric chloride. The colon was continuously lavaged with water to which various agents were added.

We also have employed it in the past, but always late and as a last resort. However, the gangrenous lesions in the colon were by then well advanced and the gangrenous process frequently extended to the operative wound and abdominal wall. This added greatly to the suffering of the patient and to the difficulty of treatment, without modifying an invariably fatal outcome. Hence the procedure was abandoned.

During the past five years we became so thoroughly impressed with the colonic lesions at the postmortem table that we again resorted to cecostomy and constant colonic lavage as soon as symptoms of colitis appeared, in the hope of combating it, but with equally disappointing results. Then the idea of performing cecostomy as soon as mercury poisoning could be established occurred to us and has been employed with encouraging results.

Our present plan is to establish a diagnosis promptly in all patients admitted with mercury poisoning, so that immediate cecostomy and constant lavage may be done, provided the patient is not in shock. We have found the electrolytic method of Booth and Schreiber,[3] which can be performed in five minutes, the most satisfactory method for the prompt detection of mercury. The older methods (Vogel and Lee) were more difficult and it often took several days before reliable information was obtained, and thus the most opportune time for treatment was lost.

[3] The electrolytic method of Booth and Schreiber (*J. Am. Chem. Soc.* **47**: 2625 [Nov.] 1925) is as follows: The current from an ordinary dry cell (about 1 volt) is allowed to flow through the specimen to be tested for five minutes, a platinum wire being used for an anode and a bright copper strip for a *cathode. The mercury, if present, is deposited as a silvery metallic film on the copper.* The method is delicate and reliable and does not require preliminary digestion. The sensitivity of the test may be increased by concentrating the specimen by evaporation. The method has been modified from that originally given by *Booth and* Schreiber, approximately 25 cc. of the specimen to be tested being used in a small evaporating dish instead of a few drops in a tissue *culture slide as* recommended by Booth and Schreiber, and also a strip of copper several millimeters in width for the cathode in place of a fine copper wire. The method is economical, dispensing with the use of large quantities of chemicals, and there are *no disagreeable fumes.*

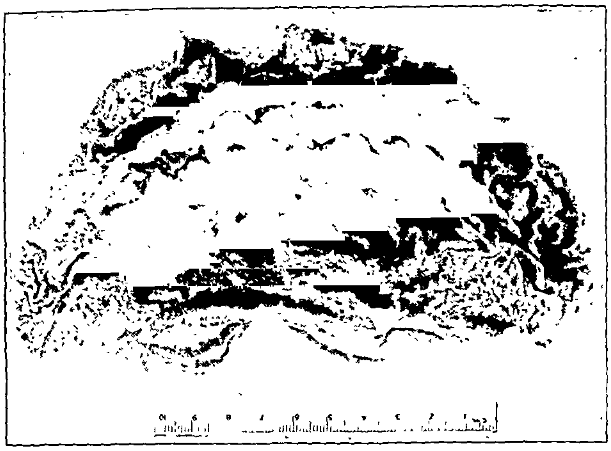

Fig. 1.—Acute hemorrhagic and gangrenous gastritis.

Cecostomy was performed in nine cases. In three, cecostomy was done on the fourth day after ingestion. All the patients died. Two patients were operated on the third day after ingestion. Both died. One patient was operated on within twenty-four hours after admission but fifty-six hours after ingestion of the poison. This patient died in shock. Three patients were operated on fifteen, nineteen and nineteen and a half hours, respectively, after ingestion. All three recovered.

Table 2.—*Chart of Operations*

Total	Died	Necropsy	Recovered
9	6	3	3

No. of Patients	Operated On	Result
1	2d day after ingestion	Died on the day of operation
1	4th day after ingestion	Died on the day of operation
1	3d day after ingestion	Died day after operation
1	4th day after ingestion	Died second day after operation
1	3d day after ingestion	Died third day after operation
1	4th day after ingestion	Died ninth day after operation
1	15 hours after ingestion	Recovered
1	[illegible]	Recovered
1	[illegible]	Recovered

Table 2 seems to indicate that the earlier cecostomy is performed, the better the prognosis.

FATAL CASES

Case 1.—S. G. took six tablets of mercuric chloride, August 10. The patient was admitted to the hospital, August 14, and a cecostomy was performed the same day. The patient died the following day. The observations at autopsy were: necrotizing nephrosis; gastritis with ulceration, and congestion of the colon. It should be noted that cecostomy was done in this case on the day of admission but four days after ingestion of the mercury.

Case 2.—L. J. took ten tablets of mercuric chloride. The patient was admitted to the hospital, June 17. A cecostomy was performed, June 21, and the patient died, June 23. The observations at autopsy were: marked necrotizing nephrosis; hemorrhagic and gangrenous gastritis, and gangrenous colitis. The cecostomy in this case was done four days after ingestion of the mercury.

Case 3.—C. N. took two tablets of mercuric chloride and was admitted to the hospital in shock, November 16. Cecostomy was done, November 17, twenty-four hours after ingestion of the mercury. The patient died in shock. The observations at autopsy were: necrotizing nephrosis, and hemorrhagic and gangrenous gastritis. The colon was normal. Blood for an examination of the chemistry of the blood was not obtained.

CASES IN WHICH THE PATIENTS RECOVERED

Case 4.—B. L. had taken nine tablets of mercuric chloride at 5:30 p. m., January 8, and was admitted to the hospital at 6 o'clock that same day. Cecostomy was performed, January 9, at 12:12 p. m. (nineteen hours after ingestion). The patient was discharged, February 11.

Case 5.—R. L. took several tablets of mercuric chloride. The patient was admitted to the hospital, September 2, at 4:45 p. m. Cecostomy was performed, September 3, at 12:20 p. m. (nineteen and one-half hours after ingestion of the mercury). The patient was discharged, September 18.

Case 6.—C. C. took one tablet of mercuric chloride, December 25, at 8:20 p. m. and was admitted to the hospital at 9:10. Cecostomy was performed, December 26, at 11:20 a. m. (fifteen hours after ingestion). The patient was discharged, January 10.

We now feel that, when cecostomy is done, if the gastric flushing is positive and the colonic flushing negative for mercury the prognosis is better than when the colonic flushing is also positive.

In many cases in which the diagnosis on admission was mercury poisoning, no mercury was recovered from the excreta. This may be explained by the fact that either no mercuric chloride was taken or the method of detection was not satisfactory. If these cases are included in statistics, it would materially bring down the mortality, and undue credit would be given to whatever plan of treatment was used. This would explain the discrepancy in the mortality rate as reported in the literature.[4]

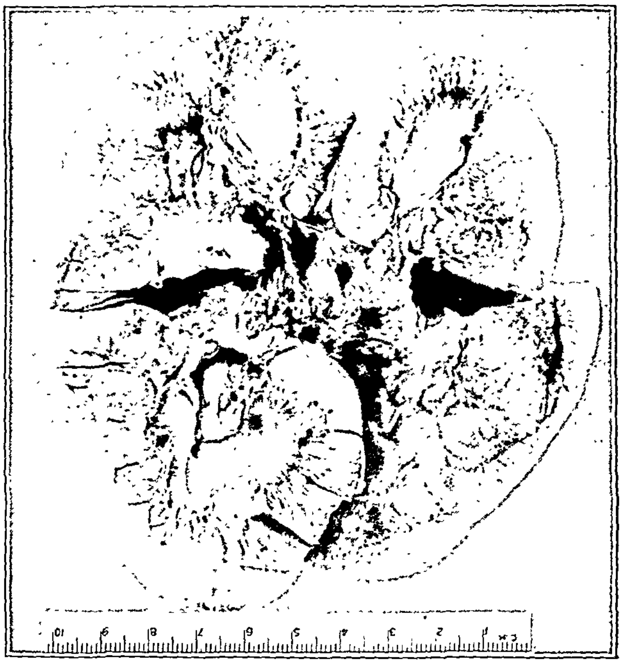

Fig. 2.—Necrotizing nephrosis.

In this series of 163 cases, 57 were proved; that is, mercury was recovered from the excreta; 106 were doubtful. Many of the doubtful cases were the earlier ones of this series, and many of them were clinically mercury poisoning but no mercury was recovered from the excreta.

---

[4] Doane (footnote 1). Lambert and Patterson (footnote 2). Schuster (footnote 2). Zeigler (footnote 2). Anderson, J. H.: Surg. Gynec. Obst. **20**: 350, 1915. Weiss, H. B.: Mercuric Chloride Poisoning, Arch. Int. Med. **33**: 224 (Feb.) 1924; Ohio State M. J. **13**: 595 (Sept.) 1917; The Principles of Treatment in Mercuric Chloride Poisoning, J. A. M. A. **71**: 1045 (Sept. 28) 1918. Goldblatt, Samuel: Am. J. M. Sc. **176**: 645 (Nov.) 1928.

The severity of the poisoning depends on a number of factors: (1) the amount of mercuric chloride taken; (2) whether the mercury is taken in tablet form or in solution; (3) the condition of the stomach, i. e., whether empty or full (one tablet taken in solution on an empty stomach will do a great deal more damage than a larger dose on a full stomach, with the time factor for initiation of treatment the same); (4) whether vomiting occurs immediately, and (5) promptness with which treatment is instituted.

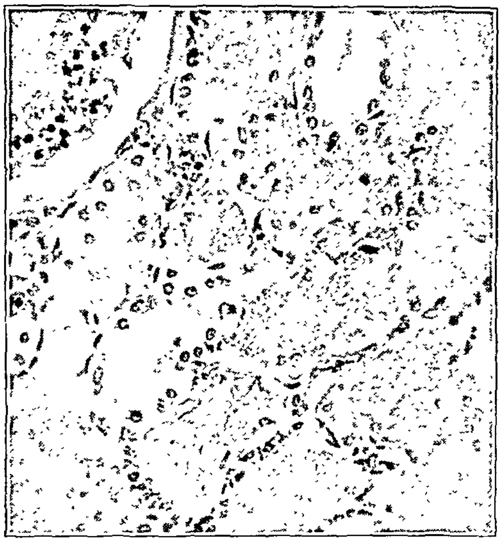

Fig. 3.—Early necrotizing nephrosis (mercury poisoning, fifty hours).

In 67 per cent of the fatal cases the patients died in the first forty-eight hours of shock. More than half of these (thirty-eight per cent) died in the first twenty-four hours (from shock). The next largest number died in the second twenty-four hours (29 per cent) of gangrenous necrosis of the stomach. At this stage, hemorrhagic and gangrenous necrosis of the stomach, cloudy swelling of the parenchymatous organs and beginning necrotizing nephrosis were noted. The colon showed congestion and edema. Two patients who died in two and one-half and three hours, respectively, showed marked alteration in the blood with increased fluidity and failure to clot. Platelet counts and clotting time were not determined. After forty-eight hours, death occurred in about even distribution as to time, up to thirteen days. Beginning with the third day, the intensity of the stomach involvement decreased, and, as early as the sixth day, advanced gangrenous colitis was present.

Table 3.—*Analysis of One Hundred and Sixty-Three Cases*

	No. of Cases	Male	Female	Recovered	Died	Autopsy	Operated On
Proved or positive	57	14	43	63	24	17	9 (6 died) (3 post) (3 recovered)
Duubtful	106	22	84	102	4	0	0

Table 4.—*Mercury Obtained*

Stomach (Lavage and vomitus)	Colon (Irrigation)	Kidney (Urine)
33 cases	18 cases	13 cases

In 21 cases, mercury was obtained from the stomach only
In 3 cases, mercury was obtained from the urine only
In 5 cases, mercury was obtained from the stool only
In the other positive cases, mercury was obtained from more than one source

Kidney damage begins promptly. Seven cases of from forty-eight hours' to seven days' duration coming to autopsy showed principally a severe necrotizing nephrosis, which was present as early as three hours after ingestion and was well marked at the end of twenty-four hours. By the end of forty-eight hours, instances of nonprotein nitrogen of 148, 158, 230, 272 mg. per hundred cubic centimeters of whole blood, i. e., a severe kidney damage with marked retention, were noted. Evidence of healing of the renal lesions in the cases coming to autopsy was noted on the ninth day. Clinically, healing was manifested as early as the sixth day, as shown by the diminution of the nonprotein nitrogen. In some cases, advanced healing had taken place by the thirteenth day with return of the nonprotein nitrogen to normal.

ANURIA

We were under the impression that anuria occurs frequently, but in this series it occurred only in six cases. Three of these patients recovered and three died. In eight other patients who died of shock in the first twenty-four hours, no urine was obtained. In how many of these anuria might have persisted, had they lived beyond the first twenty-four hours, we do not know.

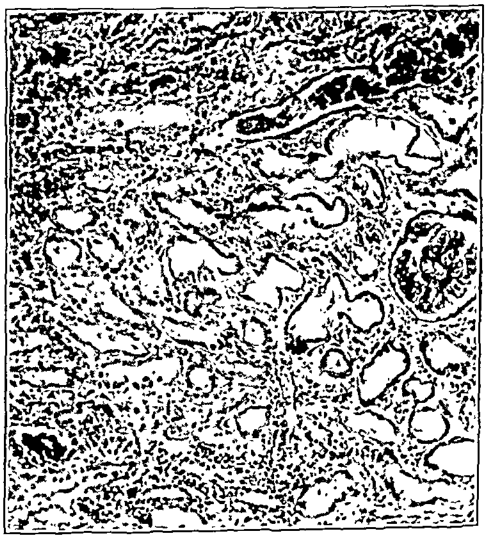

Fig. 4.—Healing necrotizing nephrosis (mercury poisoning, twelve days).

That the kidney damage alone is not the determining cause of death is shown by instances of very severe kidney damage with nonprotein nitrogen retention at the end of forty-eight hours of 148, 158, 230, 272; yet they all recovered. On the other hand, at the end of the same period, some patients who had a nonprotein nitrogen of 170 (maximum) and less died at the end of seven days, when the kidneys were already showing evidences of healing. The determining cause of death in the latter cases was found to be gangrenous colitis of considerable extent.

Gastro-Intestinal Tract: Stomatitis, pharyngitis, esophagitis and gastritis, varying in intensity are constantly present. Ulcerative gangrenous stomatitis was frequently observed in the late cases.

The chief condition referable to the gastro-intestinal tract that we wish to emphasize is the gangrenous colitis. It was present in seven of the cases coming to autopsy. The earliest it was noted in our pathologic material was fifty hours after the ingestion of mercury, when already well marked colitis was present. This patient had a necrotizing nephrosis which was the probable cause of death. In the remaining six cases, from six to twelve days (average nine) elapsed before gangrenous colitis was noted post mortem, in contradistinction to cases coming to autopsy from the second to the sixth day, when necrotizing nephrosis predominated as the cause of death. Two patients who had probable severe lesions in the colon as manifested by pain and diarrhea recovered spontaneously.

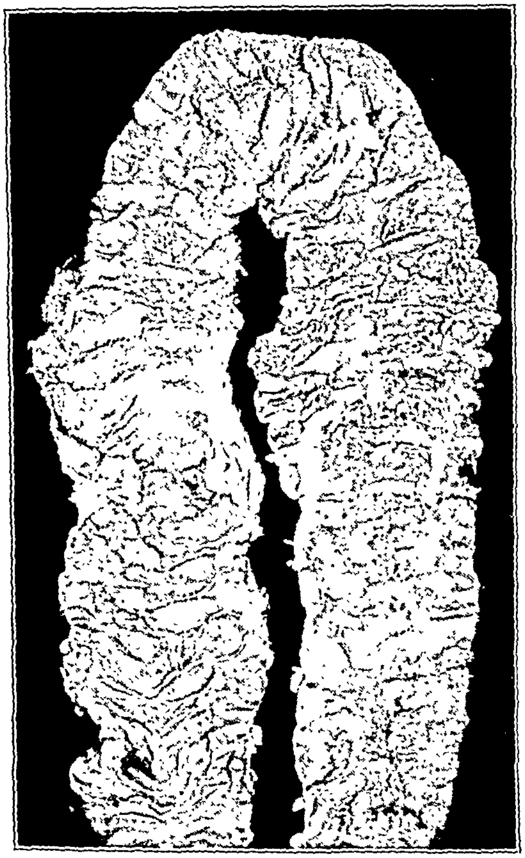

Fig. 5.—Gangrenous colitis.

COMMENT

Kidney involvement is prompt in mercury poisoning. It begins in the first twenty-four hours after the ingestion. Gangrenous colitis appears later, from six to twelve days (average nine) after ingestion. If mercury damages the kidney early and severely so that it is unable to further the elimination of the poison, then the other channels are brought into play, chiefly the colon. The minimizing of the inevitable damage to the colon through constant lavage is reasonable and sound. The earlier this is instituted, the more effective it is in preventing this serious colonic involvement.

In this series it is evident that there were three principal causes of death: (1) shock and hemorrhage which came on promptly; (2) renal damage as early as three and one-half hours after the ingestion and reaching its maximum before the sixth day; (3) gangrenous colitis, from six to twelve days after ingestion, i. e., later than the renal damage. Pathologically, it reached its maximum by the ninth day. Those cases coming to autopsy between the sixth and the thirteenth day showed the most severe lesion to be gangrenous colitis with the kidneys already in a state of advanced healing.

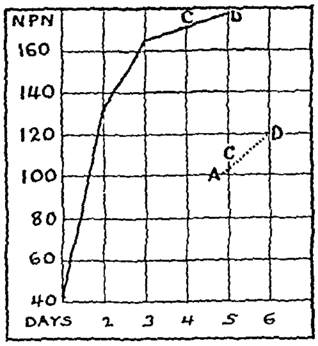

Fig. 6.—Nonprotein nitrogen in cases 1 and 2: dotted line, case 1; solid line, case 2; *A*, admitted; *C*, cecostomy; *D*, died.

SUMMARY

Analysis of 163 cases of mercury poisoning at the Mount Sinai Hospital of Cleveland reveals a number in which the patients survived the usual gastric and renal damage but succumbed to a gangrenous colitis. This lesion was apparently successfully prevented in three cases by constant colonic lavage following cecostomy done within a few hours after the ingestion of the poison.

We believe that immediate cecostomy and constant colonic lavage is the most effective measure for the prevention and treatment of the gangrenous colitis. By immediate cecostomy is meant its performance as soon as the patient is admitted, provided he is not in extreme shock. The diagnosis of mercury poisoning is first established by the detection of mercury in the gastric lavage by the electrolytic method of Booth and Schreiber, which can be done in a few minutes.

ABSTRACT OF DISCUSSION

Dr. B. S. Kline, Cleveland: The demonstration at the clinical pathologic conferences at Mount Sinai Hospital of Cleveland of a gangrenous colitis as the most severe active lesion in mercury poisoning terminating in death after the first week, after the full force of the poison had apparently spent itself and with the kidneys showing evidence of healing, was accepted as a challenge by the clinicians. The answer of Drs. Berger, Applebaum and Young to that challenge is immediate cecostomy. The colonic lesions recorded by Dr. Young are ragged, ulcerated, brownish and greenish and foul smelling.

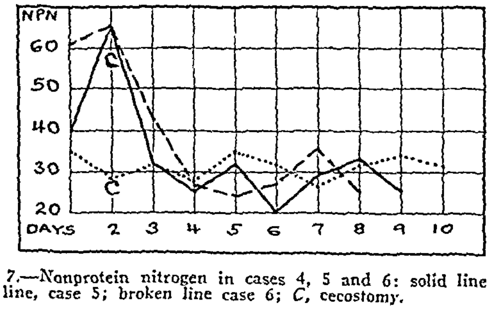

Fig. 7.—Nonprotein nitrogen in cases 4, 5 and 6: solid line, case 4; dotted line, case 5; broken line case 6; *C*, cecostomy.

Although circumscribed and on the crests of the folds at first, they extend and coalesce and finally involve a considerable portion of the inner coats of the colon. A similar lesion occurs in the lower ileum occasionally. In the lesions are found many intestinal bacteria, including filiform and fusiform bacilli, and occasionally intestinal spirochetes are present. The lesion is probably brought about in the following way: Circulating mercury is excreted not only by the kidneys but also through the mucosa of the alimentary canal. After the kidneys have been severely damaged by the heavy metal, more and more of it passes through the colonic mucosa and damages it sufficiently to allow certain regional bacteria to invade, colonize and produce the gangrenous lesion. Here, then, is a true example of the much abused phrase "the lowering of resistance of tissue." Mercury similarly reduces the resistance to infection of the gingival mucosa, sometimes even after small therapeutic doses. After the gingival mucosa is damaged sufficiently by the mercury it is invaded by oral spirochetes, fusiform bacilli and vibrios and a gangrenous gingivitis results. It is reasonable to believe that constant colonic lavage, by diluting the mercury at least after its excretion through the colonic mucosa and especially by interfering with the invasion and colonization of pathogenic bacteria, may prevent the development of gangrenous colitis.

Dr. E. B. Krumbhaar, Philadelphia: It is not for a pathologist to evaluate the possible damage of a major operation to an individual already poisoned, such as cecostomy would be in the present instance, but I wanted merely to raise that point and to suggest the possibility that it would be preferable to hold this as an interesting suggestion until Dr. Berger and his colleagues or others had obtained additional information on the subject. Their cases indicate clearly that, if the operation is to be used early, immediate cecostomy gives the best results. On the other hand, their figures and those of others show that many persons with mercuric chloride poisoning will get well under the present methods of treatment, and it is impossible immediately to have any idea whether the person is going to die or get well. In the fatal cases death usually occurs in the first forty-eight hours after ingestion of the mercury. The authors' figures showed that in the fatal cases 67 per cent of the patients died within twenty-four hours, a further 29 per cent within the next twenty-four hours. If I am correct in this, that gives the astonishing figure of 96 per cent of the proved cases fatal in the first forty-eight hours. It is difficult to believe that cecostomy will turn the tide in most of these cases, so that one is taking many patients that are going to recover anyhow, a certain number that are going to die in the first forty-eight hours, and others who are on the borderline and submitting them to what must be a serious operation, in the hope of helping a relatively small number who otherwise are going to succumb much later. My experiences at the autopsy table support the authors' statements in regard to the importance of the colonic lesions, and particularly in the case of persons dying earlier. In one of their tables it was shown that even in what one might call the kidney period there were variable colonic lesions. I have also found that even in persons dying one, two or four days after ingestion of the mercury there would be marked colonic lesions which possibly would have gone on to gangrene, so that immediate cecostomy and colonic lavage is indicated as useful right from the start for those persons who would not have died within the first day or two. I feel, therefore, that one may draw two important conclusions from the authors' interesting contribution: One is that this is an extremely interesting problem, solvable by experimental methods; the second is that until the information that such studies may give is available, it would be better to consider this procedure as still in the experimental stage.

Dr. Samuel Goldblatt, Cincinnati: It is known that in persons taking mild mercurous chloride, receiving mercury for syphilis or utilizing other drugs in which the metal occurs as a contaminant, one may find the mercury in the gastric secretions and fecal material passed by the patient for a long period. In the Cincinnati General Hospital in 1927, of some 38 patients in whom a diagnosis of mercurial poisoning was made, 19 were found not to have been given mercury at all. Of the remaining 19 patients, 15 got well and 4 died. In the 4 fatalities, all types of treatments were utilized. In my experiments on dogs, whether I gave the tablet as dry powder, in aqueous solution, in milk, with calcium sulphide, or immediately followed by sodium thiosulphate, the animals all died if they were permitted to retain the material for thirteen minutes or more. Therefore, I believe that the authors are continuing a fallacy when they state that it makes a difference whether the tablet is taken as a dry powder or in solution. My experience indicates that patients who do not retain a lethal oral dose for fifteen minutes will recover regardless of treatment. They may show severe symptoms of mercurial poisoning but no fatalities. The emesis interval is the most important index clinically and experimentally available at present which indicates whether or not a person or an animal subjected to mercury by mouth will recover. I was greatly surprised that no mention of disease of the liver was made. I have always been impressed with the marked pathologic changes in the liver. They are visible especially as a mottled, fatlike degeneration of the hepatic cells, and as a great distention of the gallbladder. I also found at autopsies of animals and in some human beings that the region of the duodenum immediately surrounding the entrance of the common bile duct was hemorrhagic, just as hemorrhagic as was the colon. Following this lead, I devised a treatment, used solely in the experimental animal, of immediate cholecystostomy. It was intended to add another portal of discharge for the mercury. It has been shown that 95 per cent of the mercury taken by mouth is concentrated in the liver within the first hour after ingestion. If, therefore, a person is actually poisoned by mercury, the treatment that produces the most rapid excretion from the liver would be the procedure of choice.

Dr. A. A. Herold, Shreveport, La.: I believe that the persons with mercurial poisoning who have come under my observation and who survived initial shock have all died by the renal route with acute suppression of urine. There have been so many of these cases that the physicians in one of the clinics in my home town have established the routine of doing an immediate renal decapsulation when they get a patient with acute mercurial poisoning who is not severely shocked. They have had good results in the cases in which they have been able to do it early. I am simply mentioning this in passing because the patients who have died in my experience have not died by the intestinal route.

Dr. Samuel S. Berger, Cleveland: Undoubtedly many patients with mercuric chloride poisoning will get well regardless of the treatment instituted. What one cannot tell is which patients will recover and which will not. We are simply recommending this suggestion to cope chiefly with one phase of mercury poisoning, namely, the factor of the colon, which we have found to be extremely important. We pointed out that there are three chief causes of death in mercuric chloride poisoning: First is shock, which occurs in the first forty-eight hours. We said that in the fatal cases 67 per cent of the patients died in the first forty-eight hours; 38 per cent of these (67 per cent) died in the first twenty-four hours, and 29 per cent in the second twenty-four hours, in shock. The treatment that is indicated is the overcoming of the shock and the elimination of the mercury, and, if the patients are not in extreme shock, cecostomy in addition. If they survive the shock, they may die of a necrotizing nephrosis. This is the second chief cause of death. We use the established methods in vogue at present for the treatment of the renal complications. We have had no experience with decortication. The reports in the literature do not seem to be encouraging. If the patients survive the renal damage, death may subsequently occur from a gangrenous colitis, which forms the third chief cause of death. The repeated demonstration by our pathologist, Dr. Kline, of gangrenous colitis as a cause of death, led us to seek some method whereby we could obviate this serious complication. We again resorted to cecostomy and lavage, which we had tried years before without results, but we thought to try it earlier, that is, as soon as symptoms of colon irritation appeared, and not as a last resort. This was followed by equally disappointing results; and then finally we tried this procedure before symptoms appeared, as soon as a diagnosis of mercury poisoning was made. Doubtless we cecostomize patients who might recover without the operation but we save a good many of them that would otherwise succumb.

It is a simple procedure and does not add to the mortality, and we feel that it is a highly useful measure and worthy of trial by others. We, too, have observed liver damage in mercuric chloride poisoning, at autopsy, but we wished to emphasize the colonic involvement as an extremely important phase of mercury poisoning, and one of the three chief causes of death, and suggested a method that is helpful in coping with it.

MELORHEOSTOSIS LÉRI: A FLOWING HYPEROSTOSIS OF A SINGLE EXTREMITY

REPORT OF TWO CASES *

ERNEST KRAFT, M.D.
CHICAGO

In 1922, Léri and Joanny [1] described a new type of hyperplastic bone lesion which is confined to a single extremity, extending from one end to the other in a linear track but usually leaving a few unaffected areas along the course. The term "melorheostosis" is derived from the Greek (μέλος, limb; ρέω, flow) and means "flowing hyperostosis of a limb." The disease was independently described three years later by Lewin and McLeod,[2] as an osteosclerosis. Other terms applied by early writers on the subject were "osteosis eburnisans monomelica" [3] and "osteopathia hyperostotica congenita (unius membri)." [4]

Tabular Description of Sixteen Cases of Melorheostosis

No. of Case	Year Published	Author	Extremity	Age	Age of Onset	Years Observed	Sex*	Shortening of Extremity	Lengthening of Extremity	Heterotopy	Histology

5 cases in Italy, 4 in Germany, 3 in United States, 2 in France, 1 in Poland and 1 in Sweden

* In this column, ♂ denotes male; ♀, female.

PATHOLOGY

The disease is characterized by proliferation of ivory-like new bone in the cortical areas. The lesions may assume different forms in different parts of the extremity, sometimes resembling osteoma, at other times suggestive of spurs, periostosis, calcinosis, or osteoplastic malignant conditions. When the proliferative process has caused considerable expansion, the hyperplastic material is of irregular wavy contour, with numerous hills and valleys, forming a linear track parallel to the long axis of the bone. Léri has likened these irregular masses, running downward from the shoulder or pelvis, to the molten stream of a candle. The sharp localization of the process to one side of a bone was compared by Lewin with a condition in which it rains on one side of the street and not on the other. The distribution does not correspond with the course of vessels or peripheral nerves.

Some observers have described stripes of dense bone within the cortex (condensed zones) encroaching on the medullary canal, but it is probable that these are really hyperostotic ridges on the surface of the cortex according to stereoscopic and tangential views. Another characteristic feature is the occurrence of bony masses in the soft parts of the shoulder or hip. These formations are irregular and partly confluent and contain negative shadows caused by islands of cartilage. In spite of bizarre features, a certain similarity in different cases is evident.

As the disease advances, pathologic products are deposited in periarticular areas, occasionally causing complete fixation of a joint. The unaffected parts of bones adjacent or opposite to the hyperostosis frequently show decalcification and rarefaction. There is rarely a bowing of the diseased bones, and, in contrast to other disorders, one finds an extreme compactness of the deformed extremity. Pathologic fracture has never been described in melorheostosis. This feature is characteristic and of importance in differential diagnosis. When the masses assume larger dimensions, pressure on nerves and blood vessels may result in transitory edema, congestion of veins, and neuralgia. Such alarming conditions, however, respond readily to immobilization and tend to disappear in a short time. Tender, indurated erythematous areas are sometimes present on the skin of the affected extremity.

Measurements of circumference of the limbs have not yielded uniform results. In some cases there is much muscular atrophy which causes decreased circumference on the affected side in spite of the fact that the volume of bone is increased. Length measurements have been done in five cases, but the procedure appears to be of no diagnostic value because asymmetry of the extremities is so common in otherwise normal subjects. Further clinical information may be obtained from the accompanying tabular arrangement.

SYMPTOMATOLOGY

The first signs are noted as a rule during childhood or adolescence. Of fourteen cases, the history began after the period of bone development in only four. Since the onset is quite insidious and the progress extremely slow, it is impossible to obtain reliable data as to the first manifestation. Muzii's[5] patient was 5 years of age and Kemkes'[6] patient, 42 years of age when symptoms began. Between these two extremes the average age of first complaint is 19 years among twelve patients. The spread between onset and first examination was twenty-nine years in the first two cases. The symptoms, even in advanced cases, may be extremely vague. In children the subjective symptoms are more pronounced than in older persons, although the roentgen observations are not as striking.

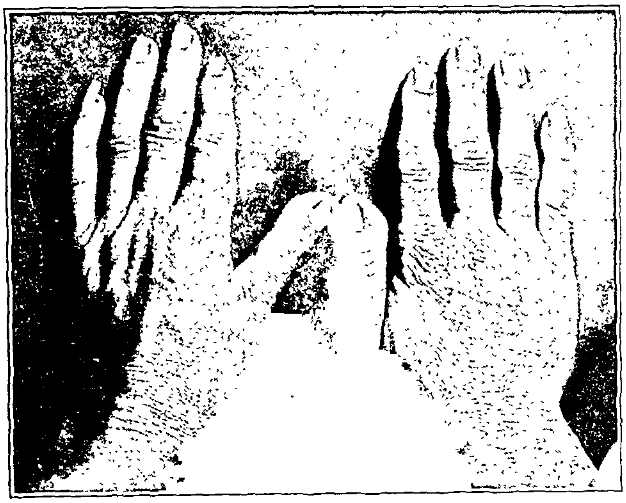

Fig. 1. (case 1).—Striking deformities of left thumb and radial side of index finger. There is a complete fixation of the first metacarpal in midposition.

The first deformities are sometimes accompanied by pain. More often they develop without any symptoms. Invariably the lesions are painful at some stage of their progress. The pain is not intense. It is provoked by strain and pressure and disappears either gradually or suddenly—sometimes for years despite persistent progress of the lesions. The most annoying symptoms are transitory stiffness and limited motion of joints, and the occasional instances of permanent ankylosis.

Case 1 (referred by Dr. E. B. Coolley in June, 1930).—H. W., a man, aged 40, a trainer of horses, during the war served as stable sergeant and contracted severe epidemic spinal meningitis. In 1910 he dislocated his left shoulder. There was no history of syphilis.

His present condition began in 1913 with a hard nodule at the radial side of the left wrist. A year later the patient discovered a small lump under the left clavicle. In 1922 the radial portion of the index finger had grown thick and uneven. Three years later his left humerus had become enlarged. In 1928 nodules appeared on the left thumb. During the last three years he has had frequent numbness of the arm on exercising and impaired motion of the shoulder. Since 1929 he has occasionally noticed a lancinating pain throughout the extremity and has been unable to bend his elbow completely. Transitory pain has also been noted in other parts of the body, especially in the right arm and hand. Lately his left thumb and index finger have become thicker and increasingly stiff. He never has consulted a physician for his condition.

On physical examination the patient appears perfectly healthy. Physical observations are essentially negative, as are also the neurologic tests, examinations of the urine and blood and chemical examination of the blood, including calcium and phosphorus. The Wassermann and Kahn tests are negative. The electrocardiogram is within normal limits.

The left shoulder is somewhat elevated. A hard, nodular, slightly movable mass, the size of an apple, bulges under the skin in the subclavicular groove. Several smaller nodules of cherry size are felt within the pectoralis major muscle. The upper arm is large and deformed. On deep palpation a wavy mass of bone is felt in the distal humerus, bulging under the biceps muscle. There is a moderate thickening of the radius. The thumb and the radial side of the index finger and the wrist show gross deformities with multiple hard nodules bulging under the skin (fig. 1).

The muscles of the left arm are slightly underdeveloped as compared with the normal right side. Motions of the left shoulder are limited as to high elevation and posterior rotation. This condition, however, varies on repeated observations. Flexion and pronation of the forearm are limited. Dorsiflexion of the wrist is somewhat impaired. There is complete fixation of the first metacarpus and impaired motion of the thumb and index finger. The two arms are of equal length. The affected humerus is enlarged, and the circumference of the left hand is decreased.

On a subsequent examination the affected arm was edematous and showed evidence of venous congestion. In March, 1931, the skin of the left arm presented multiple small erythematous areas and indurations, which were somewhat sensitive.

Roentgen examination (figs. 2 and 3) reveals a large confluent triangular mass of calcium density with irregular borders occupying the left subclavicular space, displacing the clavicle and scapula in an upward direction. The mass overlaps the coracoid process and ends with a downward spur in the anterior parts of the collum scapulae. Another spur overlaps the midclavicle. Numerous smaller nodular densities are projected into the soft parts between the upper humerus and the lateral chest wall. Another identical mass is attached to the cartilagenous junction of the first rib. The anterior humerus is occupied by hyperostotic material with irregular dented borders, while the medullary canal, the posterior parts and the condylar region are not affected. There is a slight interruption of the flow between the upper and middle thirds. The dripping-like deposits become increasingly larger in the distal parts. The hyperostosis continues in the head of the radius, involving the entire bone. The ulna shows only two small spurs below the coronoid process and a moderate posterior bowing of the proximal part. In the region of the wrist only the naviculare, lunatum, multangulum majus and minus are densified. The second metacarpal and the proximal phalanx of the index finger are involved by massive hyperostosis on the radial side, the middle phalanx showing only a slight spur. The first metacarpal and its proximal joint are wrapped in dense masses; likewise both phalanges of the thumb. The unaffected parts of the diseased extremity show varying degrees of decalcification and rarefaction.

The right forearm is slightly curved and the metacarpals of the right hand appear somewhat clumsy, leaving the impression of some developmental disturbance. All other parts of the skeleton are normal. Biopsy material is not obtainable.

Case 2, when reported by Geschickter[7] and others as ossifying periostitis, appeared so similar to previously described cases of melorheostosis of the lower extremity that it was tempting to make further studies on it. Dr.

Geschickter kindly lent his material and furnished the following information:

Case 2.—A. E. D. (a patient of Dr. O. L. Miller, Charlotte, N. C.) a white woman, aged 30, seen in September, 1923, complained of pain in the hip for the past ten days. There was just enough pain to annoy her. In 1916, when she was 23, she had pain and discomfort in the right hip. She had consulted Dr. Baer of Baltimore, who diagnosed the condition as osteomyelitis. It was suggested that she continue to use her leg. Two roentgenograms were taken. The right thigh was slightly larger than the left, and she had about 10 degrees of motion in the hip. There was good position. No operation was done, nor drainage of pus. Since 1916 the patient has considered herself well with only limitation of motion at the hip. She has not consulted a physician in the meantime about her hip. A Wassermann reaction was negative. The leukocytes numbered 14,000.

In January, 1924, the patient was well. No new symptoms appeared; the discomfort in the hip did not bother her at this time.

In April, 1930, the patient was well. A roentgenogram showed the condition in the quiescent stage.

The patient was not seen after this time. Dr. O. L. Miller of Charlotte, N. C., who has kindly cooperated, has renewed contact with the patient and examined her in May, 1931. At this time he noted but little change except for a complete ankylosis of the right hip.

A roentgen examination in May, 1931, revealed the following: The pathologic process involved the right hip and the proximal three fourths of the right femur (fig. 4). The hip was overlapped by irregular confluent shadows of calcium density. The joint was entirely obscured by the abnormal products. Smaller independent shadows were seen on the outside of the large mass between the greater trochanter and the iliac bone. The large mass covered the entire femoral neck and the lesser trochanter. It continued along the inside of the femoral shaft as a wavy ridge of the cortex. In the distal parts the mass became more uniform and regular and faded gradually away. The flowing process continued from the hip downward without interruption. No hyperostosis was seen in the leg or foot.

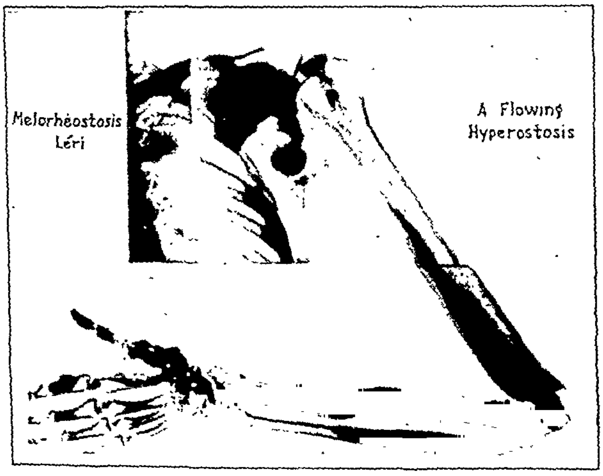

Fig. 2 (case 1).—Composite view of the left arm. Hyperostosis extends from first rib (arrows) in a continuous flow to phalanges.

The case of Meisels[8] (fig. 5) is shown for the similarity of the heterotopic masses in the inguinal region with the subclavicular formations of case 1. The inguinal mass and the hyperostotic flow differ in location from case 2 (fig. 4). The process is on the outside of the femur and extends downward to the lateral parts of the foot, while in cases with lesions on the inside of the femur the flow continues to the medial portions of the foot.

HISTOLOGY

Biopsy studies have been made in five cases. Putti found an abundance of capillary vessels which were partly obliterated. The vascular pathologic condition is a single observation and is not in accord with the observations of other investigators. Léri found a bone marrow rich in cells, islands of cartilage and primitive haversian canals. In his second case he described much irregularity and crowding of abnormal osseous lamellae in various angles. Junghagen[9] mentioned narrowing of lamellae which are elongated and poor in cells. There was, however, always a regular concentric arrangement around the haversian canals. Kauffmann[10] studied Zimmer's case histologically and corroborated the finding of a primitive bone tissue.

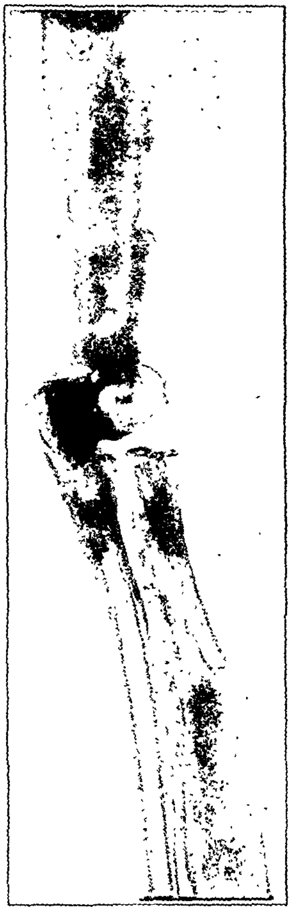

Fig. 3 (case 1).—Anteroposterior view. The hyperostotic spurs of proximal radius and ulna, which are well seen in figure 2, appear like intracortical zones of condensation.

ETIOLOGY

Four theories have been advanced to explain the etiology; vasomotor neurosis, infection, endocrine-constitutional disturbance, and embryonic defects.

1. Putti considered the isolated observations of eosinophilia and of abundant, partly obliterated, capillaries as significant for a lesion of the sympathicus. In his opinion the nutrient arteries were primarily involved, since the dense lines were parallel to the main axis of the bone. With his theory another discussion has been opened: Does vascular obstruction cause sequestration and secondary eburnization of bones, or is an increased blood supply responsible for sclerotic bone changes? Putti's theory does not explain the involvement of small bones, of soft parts in shoulder and hip and the selective distribution.

2. Léri advanced the theory of an infectious agent. He believed that the cutaneous phenomena were caused by embolism, but he did not succeed in isolating parasites. Material transplanted into apes was absorbed in less than a year.

3. The coincidence of Meige's trophedema in the case of Meisels and Goldschlag[11] with the presence of hyperthyroidism and hypopituitarism led to the endocrine-constitutional theory. A craniostenosis in Putti's

case and a slight developmental disturbance of the opposite arm in my case (case 1) may substantiate these ideas. Such observations, however, are too infrequent to allow definite conclusions.

Hereditary factors do not play a dominant rôle. The histories are negative in this respect except for a "crippled" hand of the grandfather in Zimmer's case.

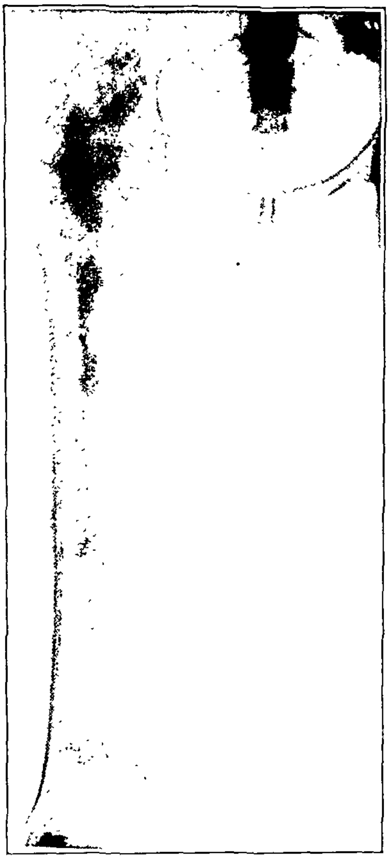

Fig. 4 (case 2).—Characteristic flowing hyperostosis of proximal three fourths of the right femur with heterotopic masses over the hip joint. In Muzii's case the flow extended on the same side downward to the first metatarsal, while in the other cases the lateral parts of the entire extremity were involved.

4. An explanation of the selective linear distribution of pathologic changes is found in Zimmer's theory of a metameric disturbance. Zimmer thought that the hyperostotic bands could be traced to a single truncal segment and he assumed an embryonic lesion prior to the budding process of the extremity. Apparently undifferentiated cells of a metamere become isolated and remain dormant until later in life after they have spread over the limb. These groups of cells seem to lack a synchronous formative stimulus and produce a primitive type of bone according to microscopic observations. Large deposits of calcium are further evidence of their primitive character.

In connection with the embryonic theory, however, some fundamental facts have to be considered. The belief that limbs originate mainly from fused truncal segments is based on the distribution of nerves and their relation to spinal segments by means of the plexus. On the other hand, animal experiments do not support the theory of a metameric construction of extremities. The studies of Harrison,[12] Byrnes[13] and Mangold[14] on amphibia and fish have shown that the unsegmented mesoblast of the somatopleure is a primary factor in the formation of limbs. Lewis[15] has demonstrated that injury to myotomes in the limb region of amblystoma, while producing muscular defects, has no effect on the development of the limb itself. When undifferentiated cells of limb buds and other mesodermic tissue are transplanted to other parts of the trunk, perfect extremities develop and the nerves of these artificial limbs communicate with the spinal ganglions by means of a newly formed plexus. Experiments on higher vertebrates are still lacking in view of the technical difficulties, but so far embryologic studies have failed to support the metameric theory and the exact nature of melorheostosis is still unexplained.

COMMENT

The question of selectivity of a single extremity still awaits a definite solution. Although Léri emphasized the isolated occurrence as characteristic, he observed in his first case the development of heterotopic nodules on the opposite side. Do potential foci of hyperostosis remain dormant in parts of the extremity and in other limbs? Seth Hirsch[16] in his excellent discussion of osteitis fibrosa correlates similar bilateral pathologic conditions with Léri's disease. His view is partly supported by observations of a constitutional disturbance. There is some similarity with a generalized bone disease: infantile osteopathia hyperostotica multiplex—independently described by Engelmann[17] and Seth Hirsch, but additional observations are necessary to decide the question of a generalized involvement.

DIFFERENTIAL DIAGNOSIS

Considering the characteristic features, one may find little difficulty in differentiating the disease from other bone disorders of inflammatory and dysplastic nature. Tuberculous and syphilitic osteitis can be ruled out by history, physical examination and serologic tests. Also malignant neoplasms have to be disregarded in the absence of additional observations.

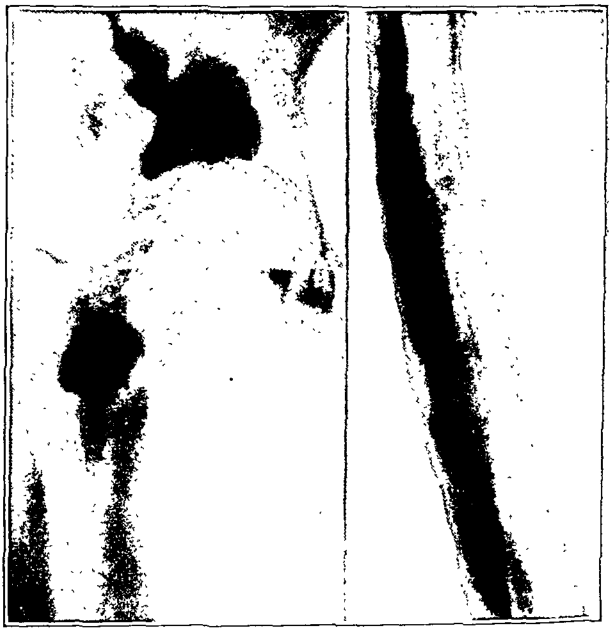

Fig. 5.—Reproduction of Meisels' case (by permission of author). There is a striking resemblance of the subinguinal shadows *with the subclavicular masses of case 1 (compare with figure 2).* The hyperostotic bands are located on the outside of the femur in contrast to the medial course in case 2 (fig. 4).

PROGNOSIS

The disease usually shows a very slow progress and may become stationary for years. The prognosis is favorable. There has never been any evidence of a malignant character. These facts should be kept in mind before any radical therapy is attempted.

TREATMENT

No definite therapeutic achievements have been reported. Because of the meager symptomatology the patients are frequently hesitant in submitting themselves to therapy. Surgical correction is rarely indicated. Valentin[18] and Kahlstorf[19] reported relief from heat and physical therapy. In case 1 an improvement was observed when repeated roentgenograms were taken in one session. One has to keep in mind, however, that spontaneous remission of symptoms is a characteristic feature of the disease. It would be instructive to apply radiation therapy systematically. One might then gain a better knowledge of the biology of the abnormal cells and subsequently of the unexplained pathogenesis.

ABSTRACT OF DISCUSSION

Dr. Philip Lewin, Chicago: My interest in this subject dates back to 1923, when Dr. MacLeod showed me a set of roentgenograms of a patient whose case I reported before the American Orthopedic Association in 1925. I searched the literature without success. Then I showed the films to the leading orthopedic surgeons in eleven countries, to many roentgenologists, to neurologists, and finally to Sir Arthur Keith in London. No one was able to classify the condition for me. Some time later, Putti sent me a reprint of an article he wrote on the subject. Then I received a reprint from Léri. Within the last three weeks, I had a long discussion in Paris with Lièvre, an associate of Léri, who is publishing a monograph on the subject. He has collected fifteen cases. He has no conception of the etiology. His experimental work was inconclusive. The theories that one should consider are the neurogenic, myogenic, vascular, metameric and endocrine.

Dr. H. K. Pancoast, Philadelphia: I should like to ask whether there has been any particular study along the line of parathyroid tissue disturbances in these cases. When one analyzes the appearance, in a way it seems to be just the opposite from that which is seen in certain parathyroid cases. The question arose in my mind as to whether a parathyroid hormone had been used experimentally in any case of this kind. There is also a certain similarity in the appearance between this condition and the one that has been described as osteopoikilia by Ledoux-Lebard, in which one sees the small round spots distributed apparently through the medullary portion of the bones in certain portions of the body, especially the pelvis and upper femurs, and even in the lower portion of the lower extremities and in the hands.

Dr. Leon T. Le Wald, New York: Dr. Kraft kindly showed me his case. At first glance I thought it was related to the condition known as calcinosis, but careful study of calcinosis, of which I have had two cases and have seen two others, showed that in calcinosis the calcium deposits are distinctly separate from the bones, although where the masses of deposits of calcinosis are very large they might simulate to a casual observer the possibility that they were related in some way to a bony lesion. I am convinced that there is no relationship unless, as Dr. Pancoast suggests, all these calcium changes are associated with parathyroid disease. Otherwise I should say that calcinosis is in no way related to this particular condition of melorheostosis.

Dr. Ernest Kraft, Chicago: In regard to Dr. Pancoast's remarks, I do not remember any literature on the parathyroid in connection with the disease. Meisels found hyperthyroidism in his case—a single observation which has probably no relation to the bone condition. A theory of the parathyroid would not explain the peculiar distribution over a single extremity. Osteopoikilia, or spotted bones, has been mentioned in the differential diagnosis. The process is within the bone and not expansive. Its distribution is more general, while melorheostosis is confined to one limb. In regard to Dr. Le Wald's remarks on calcinosis, I agree that there is some resemblance. However, calcinosis does not show hyperostosis and presents different histologic changes.

ACUTE STAPHYLOCOCCAL INFECTIONS OF THE KIDNEY

THEIR CLINICAL ASPECTS AND TREATMENT *

REED M. NESBIT, M.D.
ANN ARBOR, MICH.

This paper deals with the discussion of a series of forty-eight cases of acute staphylococcal kidney infection observed and treated at the University Hospital during the past three years. Certain facts concerning the pathology, diagnosis, relationship to secondary invading organisms and treatment that are brought out by these cases are felt to be of particular interest.

The cases here reported did not have any apparent preexisting infection of the urinary tract and were uncomplicated by any discernible obstructive lesions.

INCIDENCE

The staphylococcus is present in a surprisingly high proportion of infections of the urinary tract. Young[1] found it in 49 per cent of 356 cases studied. Helmholz[2] found 15 per cent of all cases studied at the Mayo Clinic to be due to some form of the coccus. Kretschmer[3] found the staphylococcus in 20 per cent of 200 cases uncomplicated by stone, tumor, stricture, prostatic enlargement or tuberculosis. Rovsing[4] in a similarly controlled series found the staphylococcus in 25 per cent of cases. Hellström[5] in 507 cases found it in 30 per cent.

For this series of acute infections the age incidence ranged from 4 to 49 years, the average being 26. Sex incidence showed a preponderance of males, 31 to 17. Involvement of the right side was seen thirty-one times and of the left twelve, with bilateral involvement occurring in five instances.

ETIOLOGY

The question of etiology has been in the past the subject of much study as well as of no little controversy. Since the days of Albarran,[6] who accepted the hematogenous as the most probable route in this type of renal inflammation, which he first described, others have established the fact without question. The contributions of Ekehorn,[7] Legueu,[8] Koch,[9] Runeberg,[10]

Brewer,[11] Cunningham,[12] Cabot and Crabtree[13] and, more recently, those of Bumpus and Meisser[14, 15] are of particular importance.

In our series, thirty-four cases, or 67 per cent, showed definite foci considered as directly responsible. Of this group, fifteen were acute inflammations of the ear, nose and throat, five were boils, three followed "catheter chill" and three defloration with chill. In regard to the last two factors, the recent work of Scott[16] at the Brady Institute in Baltimore is of great significance. He demonstrated transient positive blood cultures in eighty-two patients having reactions following instrumental or operative manipulations of the genito-urinary tract. In twenty-four cases showing positive cultures of staphylococci, the same organisms were subsequently recovered from the urine. Trauma was an etiologic factor in but one of our cases.

PATHOLOGY

Grossly, the kidney is enlarged from congestion and edema, with multiple small areas of suppuration disseminated throughout the cortex. These small abscesses may enlarge to varying degrees, rarely even involving the entire parenchyma. These more extensive suppurative processes have been described by many authors, who have applied the terms abscess of the kidney, acute renal suppuration, septic infarct of the kidney and renal carbuncle to the lesion. While these severe degress of renal suppuration do occur, I feel that they are extremely rare. Young,[17] Cabot,[18] Bugbee,[19] Baker,[20] Bolton[21] and Hellström[5] are but a few of those who have shared this opinion. Rupture of a cortical abscess through the renal capsule with subsequent perinephric suppuration is a common sequela. The medullary zone rarely shows infection of importance, while the pelvis is practically never inflamed.

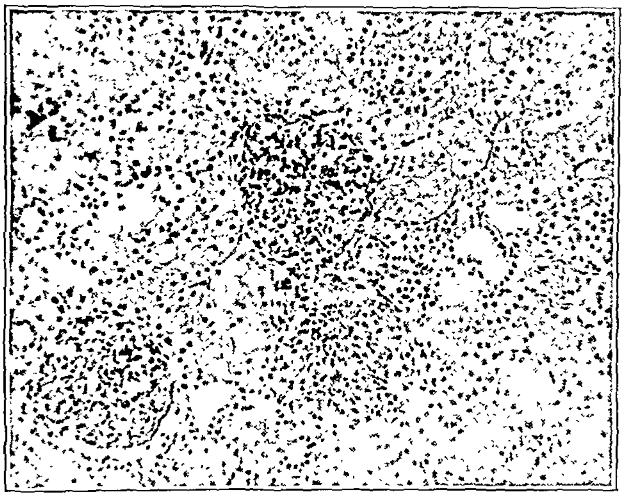

Fig. 1.—Three glomeruli showing active early inflammation with fibroblastic proliferation and increase of wandering cell nuclei. Fusion of capillary loops and Bowman's capsule. (High power; hemalum eosin stain.)

Microscopically, it is apparent that the initial lesion is a glomerular one, from which the inflammatory process extends. Albarran,[6] Rovsing,[4] Brewer,[11] Cabot and Crabtree,[13] Young,[1] Chown,[22] and Wilson and Schloss[23] have amply demonstrated these facts. Characteristically there are many of these microscopic areas of suppuration throughout the cortex. The location of the lesion undoubtedly explains the rarity of pyuria. That healing takes place rapidly has been clearly demonstrated microscopically. The great vascularity of the cortical zone is probably to a large measure responsible for this rapid and complete healing of the infected areas. Photomicrographs made of sections removed from the renal cortex of patient 47 demonstrate all stages of the process, including almost complete healing. The specimen was removed on the eighth day of this patient's illness, when a small perinephric abscess was drained. Wilson and Schloss[23] have shown that when complete healing has occurred there is little evidence of important damage to the renal parenchyma, although microscopic scars are to be seen.

SYMPTOMS

In this series the mode of onset, general symptomatology and progress of the disease have shown a striking uniformity. In all but three instances the onset was abrupt, with pain as the initial symptom, generally accompanied by a chill.

Pain and costovertebral tenderness were present in forty-seven of the forty-eight cases. The pain is generally of moderate severity, typically renal in its location, and constant and aching in character. If extremely severe, it may simulate renal colic, radiating down the course of the ureter to the genitalia. Bladder irritation occurred in but half of our cases. Chills occurred during the course of the disease in thirty-four instances.

Constitutional symptoms of infection are the rule. These include loss of appetite, malaise, general weakness, occasionally prostration and rarely nausea and vomiting. High fever is the rule, many patients having a temperature of 104 or 105 F. The temperature characteristically runs an irregular course as in sepsis elsewhere. The average high temperature in our series was 102 F.

Leukocytosis is constant, not infrequently being high. The lowest count is this series was 9,200, and the highest 33,000. The average was 16,400.

URINE

Gross hematuria accompanied the onset of symptoms in eight cases of this series. In each instance it was of less than forty-eight hours' duration. Microscopic hematuria is by no means uncommon. A trace of albumin is the rule.

In every instance the staphylococcus was demonstrated in the urine by staining the sediment, although in some instances its appearancce followed the onset of symptoms by several days. In regard to culture of the urine, it is of interest that in three of our cases repeated cultures were negative in spite of large numbers of the organisms being readily demonstrable in the stained sediments. This is by no means an original observation. Cabot and Crabtree,[13] Helmholtz[24] and Hellström[5] have commented on it. Helmholz[24] has suggested that the bacteria in such cases have possibly been rendered sufficiently devital to fail to respond to the usual culture methods. Hadley[25] has found that during certain phases of development of typhoid, paratyphoid, Shiga dysentery and other organisms it is impossible to grow them satisfactorily on any of the known mediums. He has suggested that some such phase of development has been here encountered in the staphylococcus. In either event it would seem that the method of study of centrifugated specimens by stain could be depended on for accurate diagnosis with greater certainty than by culture.

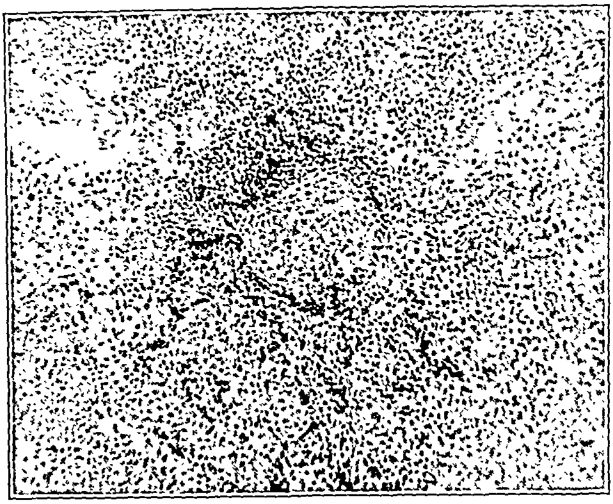

Fig. 2.—Advanced inflammation. Marked leukocytic infiltration surrounding the glomerulus and its capsule. (High power; hemalum eosin stain.)

Less than half of the patients in this series showed leukocytes in the urine at any time during their illness. This absence of cells often leads to incomplete study of the urine, with consequent failure to demonstrate the organisms. Some of the cases here recorded were said to show negative urines by virtue of that error. Subsequent stain of the suspected sediment in these instances revealed the organism.

Secondary invasion of the urinary tract in coccal infections has been long observed and commented on. Rovsing,[4] Clarke[26] and Maxwell[27] as early as 1898 attempted to solve this problem. Their investigations were not rewarded by positive conclusions, though in general they all felt that the coccus so lowered the resistance of the urinary tract that Bacillus coli found a favorable soil for invasion. This view has been shared by many subsequent writers. Chown[22] suggested that the kidney, in overcoming the primary invader, lays itself open to attack by the secondary invader. Bumpus and Meisser[14] have tended toward this view. Helmholz and Millikin[28] conducted animal experiments in which they first produced staphylococcal infections but failed in every instance to produce secondary invasion of the kidney with B. coli. In our series, secondary invasion by the colon bacillus occurred in seventeen instances, appearing from about the seventh to the tenth day and tending to persist longer than the primary invader. With the invasion of the colon bacillus, pus cells always appeared in the urine.

In this series the urine became free from signs of infection on the seventh day in the most favorable instance, the longest being 120, with an average of 35 days.

DIAGNOSIS

Ordinarily, the clinical diagnosis is arrived at without difficulty or delay, except in those rare cases of doubt in which the urine fails to show the cocci for the first few days. In these instances costovertebral tenderness is the most important observation.

Differentiation in atypical cases is sometimes difficult. The lesion most commonly confused is acute appendicitis. The absence of nausea and vomiting and of muscle spasm, with the presence of costovertebral tenderness and high leukocytosis, generally suffices to make the differentiation, even though cocci have not yet appeared in the urine. The tenderness in the right lower quadrant sometimes seen in these patients is probably due to some degree of inflammation of the ureter. This is ordinarily not accompanied by any muscle spasm.

Acute hydronephrosis must be ruled out in some instances. Four of our patients (8, 18, 25, 31) complained of extremely severe renal pain simulating colic and suggesting acute obstruction of the upper urinary tract. Ureter catheterization and roentgen studies were utilized in these instances to establish the diagnosis.

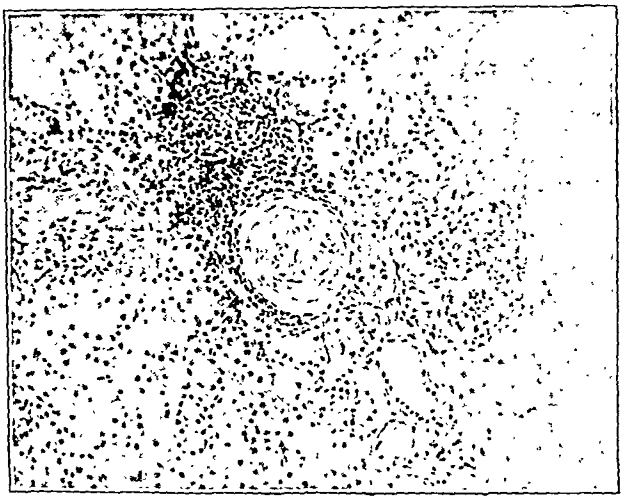

Fig. 3.—Moderate healing. Advanced scarring of glomerulus and thickening of its capsule.

Acute cholecystitis at times offers a difficult differentiation. For example, patient 44, a graduate nurse, was admitted during an attack of excruciating pain in the right upper quadrant, radiating to the back, with associated nausea and vomiting. She was in an extremely toxic condition, having a temperature of

103 F. There were two severe chills. No urinary symptoms were noted. Examination showed spasm in the right upper quadrant and exquisite tenderness. There was also acute right costovertebral tenderness. The leukocytosis went from 11,000 to 33,000 in forty-eight hours, with a corresponding increase in the severity of symptoms. The urine was repeatedly found to be negative to all tests. Although coccus kidney was strongly suspected, acute empyema of the gallbladder could not be ruled out, and a laparotomy was performed at the beginning of the third day. All abdominal viscera were found to be normal. The kidney was enlarged to palpation through the peritoneum. On the second postoperative day, showers of cocci appeared in the urine, confirming the diagnosis of coccus kidney made in the operating room. The symptoms and signs

had all cleared up by the fourteenth postoperative day, although the urine showed organisms for approximately a month.

COMPLICATIONS

The relationship of coccus kidney to perinephric suppuration has long been recognized. Richardson,[29] Braasch,[30] Mayo,[31] Gibney,[32] Townsend [33] and many others have regarded these kidney infections as the most common cause. This complication arose four times in the forty-eight cases treated at the University Hospital. Other cases of perinephric abscess were of course observed and treated during this period but obviously should not be included in this series. The onset of this complication is heralded by a definite increase in intensity of symptoms and signs, especially local pain and tenderness, and is associated with an increase in temperature as well as leukocytosis. The diagnosis is rarely difficult in cases in which its onset is watched for carefully.

So-called carbuncle of the kidney is a complication which I feel is extremely rare, although many isolated cases have been reported in the literature.[34] Aside from the extreme rarity of this lesion, its diagnosis when it does occur should, I feel, offer little difficulty. The severity of symptoms should invariably indicate a situation demanding surgical relief. Beer[35] has described a few very unusual instances of this type, however, which have been silent so far as acute symptoms and signs are concerned. It is of interest and, I believe, of diagnostic importance that practically every case of carbuncle of the kidney reported in the literature presented a history of from three to nine weeks' illness prior to diagnosis and operation. In practically every instance a coexisting perinephric abscess was found. One is led to speculate as to whether early diagnosis and drainage of the perinephric abscess might not in many instances have prevented the widespread renal suppuration that was found. Habein,[36] in commenting on a series of forty-three cases of perinephric abscess observed at the Mayo Clinic, pointed out the importance of early diagnosis and treatment to prevent renal destruction and general sepsis. In the series mentioned, the average duration of symptoms before diagnosis was from five to six weeks.

COURSE OF THE DISEASE

Characteristically, staphylococcal infections of the kidney run a stormy course for the first week, followed by marked improvement of all symptoms and signs. Usually by the fourteenth day the temperature has come to normal and the patient is free from pain. Secondary invasion of the urinary tract by B. coli, when it does occur, usually takes place in the second week and generally produces some degree of bladder irritation or intensifies any preexisting urinary symptoms. Some patients show a slight recurrence of fever on being allowed up after their symptoms have disappeared. This rise is always a transient one, passing off in from twenty-four to forty-eight hours. In this series the average duration of symptoms was 14.4 days. When the lesion fails to run a satisfactory course in a reasonable period of time, one of the complications must be suspected. Of special significance in this regard is any marked accentuation of any of the symptoms or signs.

The uncomplicated cases apparently end in complete recovery, except for the undoubted glomerular scars, which probably have no importance so far as renal function is concerned.

One of our cases, showing a bilateral fulminating infection, terminated fatally. Postmortem examination revealed only suppurative lesions of microscopic dimensions.

In the cases here reported, it is of interest to note that in no instance did the acute staphylococcal infection become chronic, a point stressed by Hellström[5] in analyzing his series of thirty acute cases. On the other hand, in eighty cases of chronic staphylococcal infections he found that the onset was almost invariably insidious. Our observations made on a considerable number of the same type not here reported have tended to substantiate his views.

TREATMENT

Most of the earlier writers on the subject have advocated and practiced various operative procedures designed to drain the cortical abscesses, to prevent widespread renal sepsis or even to save life. The operations advised have consisted of some form of drainage of the suppurating areas, by puncture, incision or excision generally with decapsulation. Nephrectomy has also been advocated. Many, however, have reserved this for desperate cases.[37]

In our management of these patients, we have consistently followed a conservative course, considering the disease to be one which tends to run a self-limiting though stormy course within a relatively short period of time in the vast majority of cases. In uncomplicated cases, patients with surprisingly serious infections recover without operation quite rapidly.

In one of our cases surgical drainage of three small cortical abscesses was performed, the preoperative diagnosis being perinephric abscess. Recovery was prompt and complete. In retrospect we doubted the value of the operation, feeling, as Bugbee[10] did in an identical situation, that the patient would undoubtedly have recovered spontaneously.

Our patients were kept in bed during the febrile period, fluids were forced, and the diet was regulated by the patient's desires. Various medications were given orally in most cases but have not clearly demonstrated their worth.

Complications should be treated surgically without delay. The only one occurring in this series was perinephric abscess, occurring four times and representing an incidence of 8.3 per cent. In each instance the diagnosis was promptly made and surgical drainage was instituted with rapid recovery.

SUMMARY

1. Acute staphylococcal infections of the kidney are relatively common.
2. They are hematogenous in origin, a recognizable focus generally being present.
3. The parenchymatous lesion is characteristically cortical in its location and shows a marked tendency to heal promptly and completely.
4. Costovertebral pain and tenderness are constant.
5. Examination of the stained urinary sediment is essential in all suspected cases.
6. The disease tends to run a stormy though self-limiting course, ending in complete recovery.
7. Surgical treatment should be employed only in cases in which complications develop, of which perinephric abscess is the most common.

The Abnormalities of Human Beings.—As doctors, our thoughts and energies are concentrated on the abnormalities of human beings. There is no separation of man from his disease or of disease from man. The two are part and parcel of a single unit which needs some further definition for our purposes. What we recognize and classify as a disease picture is, in reality, the kaleidoscopic reactions of a man to some injury. This injury may take the form of invasion of the body by bacteria, the disturbance of the specific function of some organ (diabetes, Graves' disease), or a mechanical defect such as occurs in heart disease.—Longcope, W. T.: Methods and Medicine, *Bull. Johns Hopkins Hosp.* **50**:4 (Jan.) 1932.

INFECTIONS IN THE GENITO-URINARY TRACT, AND COMPLICATIONS

FURTHER ADVANCES IN THE TREATMENT *

HUGH H. YOUNG, M.D.
J. A. C. COLSTON, M.D.
AND
J. H. HILL, M.S.
BALTIMORE

The treatment of infections of the genito-urinary tract depends so much on the type of bacterium which is causing the infection that it seems important to present briefly summaries of the bacteriologic observations from a consecutive series of our cases of bladder, kidney and blood stream infections.

INCIDENCE OF INFECTION

Bladder Infections.—A summary of the observations in a series of 600 cases of bladder infection shows that 351 cases, 58.7 per cent of the series, were infected with colon group organisms, 253 of which were obtained in pure culture. The staphylococci and micrococci were found in 265 cases, in pure culture in 122. After these two big groups there is a rapid drop in incidence. Streptococci were found in 67 cases, 30 of them in pure culture. Although found comparatively seldom, the remaining organisms are by no means unimportant on that account. Among them may be cited Proteus, found in 43 cases, 17 times in pure culture; B. pyocyaneus found in 28 cases, 16 times in pure culture; 6 cases of infection with organisms of the paratyphoid group; 5 cases of infection with organisms of the dysentery group, and 3 of the typhoid group.

Renal Infections.—A review of eighty-two renal cultures covering the same period showed a general parallelism to the bladder series, with certain exceptions. Thus the incidence of colon group infections is lower in the kidney than in the bladder; that of the streptococci is the same. Both Proteus and B. pyocyaneus show higher incidence in the kidney than in the bladder. The same is strikingly true of Staphylococcus aureus, and of the organisms of the paratyphoid group. Certainly the presence of Proteus or of B. pyocyaneus or of the many interesting intermediates of the typhoid-paratyphoid-dysentery groups is not to be regarded lightly.

Blood Stream Infections.—An analysis of 203 cases of blood stream invasion in our cases shows the following incidence: There were 104 cases of colon group invasion, after which there was a great drop, to 27 by members of the staphylococcus or micrococcus groups, 18 Proteus, 9 by members of the typhoid group, 7 by B. pyocyaneus, 5 by the paratyphoid group, 4 by beta streptococci (hemolytic), 4 by gamma streptococci, and 25 in which two organisms were found.

In a previous paper[1] the point was made that in differentiating colon group bacilli, whereas the number of organisms of the B. lactis-aerogenes group (genus Aerobacter) in the intestine is low, varying according to different observers from zero to not more than 26 per cent, in the urine, in a series of 200 cases, the incidence of this organism was about 40 per cent. In the blood the incidence is about 75 per cent of the colon group invasions.

Among the general considerations of interest in the treatment of infection is the problem of the difference of resistance of different bacterial genera to drug action. Thus even among the colon bacilli group there is a striking difference in the inhibitory action of drugs on the two main subdivisions; that is, the organisms most closely related to B. coli, or the genus Escherichia and the organisms of the B. lactis-aerogenes group, or the genus Aerobacter. The accompanying table shows how striking is the difference in action of powerful drugs in their action on these two main groups. B. pyocyaneus has proved by far the most resistant vegetative organism that we have tested. It is wise to determine these general facts before drawing conclusions about any one drug.

Proteus Infections.—Cases of Proteus infection, although less numerous than the coccal or colon group infections, are often of extreme importance. It has been noted that the mortality of Proteus blood stream invasions is 55 per cent. The organism is also the cause of very serious damage in operative wounds, which are usually accompanied by a certain amount of general sepsis. Such Proteus infections not only greatly retard the healing processes but may be associated with very serious systemic and general symptoms. The same applies to infections with B. pyocyaneus and B. thompsoni. The treatment of the open wound and bladder which have become infected with these alkalizing bacilli has shown at our clinic that they are best combated by an active use of irrigations or injections of 1 per cent solution of acetic acid, at the same time giving acidifying drugs by mouth, acid sodium phosphate and the like.

Concentrations of Drugs Invariably Inhibiting Growth in Broth

Drug	Escherichia	Aerobacter
Mercuric chloride	1:500,000	1:30,000
Meroxyl	1:300,000	1:20,000
Merthiolate	1:900,000	1:400,000
Metaphen	1:300,000	1:80,000
Potassium mercuric iodide	1:200,000	1:70,000

THERAPEUSIS

The difficulty of completely eradicating infections of the genito-urinary tract is due to the fact that the bacteria have usually penetrated so deeply that local treatment, whether of the urethra, bladder or kidney pelvis, usually fails to reach the depths of the infection. Although numerous new germicides have been produced, the problem still remains of how best to eradicate deep seated foci of infection.

For many years internal therapeusis by oral administration of drugs has been used, sometimes effectively; but, as a whole, this method has failed. With the development of intravenous chemotherapy, protein and serum therapy, both specific and nonspecific, and shock therapy, much has been accomplished. But, owing to the great difficulty of correctly interpreting results and of evaluating the effect that may be attributed to the treatment, it is often difficult to state positively just what has been and can be accomplished by the different types of therapy. In spite of these great difficulties, we will describe certain methods employed in the treatment of various types of genito-urinary infection, attempt to analyze the results, and draw conclusions as to the efficacy of the treatment.

Gonococcus Infections.—These represent a notably difficult therapeutic problem. Whereas a certain percentage of patients with acute gonorrhea are cured or spontaneously get well by simple local or internal therapy, it is well known that in a large proportion of the cases the organisms penetrate deeply into the glands remote from the urinary passages, where they may remain for indefinite periods. The problem here is, from the very beginning, to reach the bacteria which so rapidly penetrate first into the glands along the urethra and then the deeper glands of the bulb, the prostate, the seminal vesicles and not infrequently the epididymides, the blood stream, the joints, and even the heart. Even in the simplest cases of anterior urethritis, the gonococcus is generally to be found in the periurethral glands too distant to be reached by local injections, and, although the deeper organs may never be reached, the infection may remain chronic for many months or years. Consideration of these facts led us to use a combination of local and intravenous therapy, even in cases in which the infection was only a few hours or a day or two old, and we are thoroughly convinced, after a considerable series of cases, that far better and quicker results are obtained by a combination of local antiseptic therapy, injections and irrigations, and intravenous therapy, with mercurochrome-220 soluble or neoarsphenamine, alone or in combination with protein therapy, than we have ever been able to accomplish by local treatment alone.

We are presenting herewith the histories in brief abstract of fourteen cases of acute and chronic gonorrhea, many with complications, to show what may be accomplished in some cases by intravenous mercurochrome. The diagnosis of the gonococcus was always made by the Gram stain or by culture. All the patients received local treatment for urethritis consisting of injections of mild silver protein, strong silver protein, mercurochrome or intravesical irrigations of permanganate or meroxyl in addition to intravenous injections of 1 per cent mercurochrome in doses stated, over a given time. Lack of space prevents giving many details, but all important facts have been noted. In no case were the reactions very severe, nor was there any resultant nephritis or enteritis; the statement may therefore be accepted for each case that the intravenous therapy did no harm. The splendid results obtained speak for themselves. The failures are given in the summary of results.

Case 1.—*Acute gonococcus urethritis.*

W. N. B., a man, aged 32, admitted Nov. 12, 1929, had a urethral discharge of twelve days' duration. The first glass of urine was very cloudy. The prostate and the seminal vesicles were normal. Injections of 13, 15, 18 and 20 cc. of 1 per cent mercurochrome were given intravenously during a period of ten days. Anterior injections of 1 per cent strong silver protein and bladder irrigations of acriflavine hydrochloride, 1: 4,000, were given. Two days after the first injection the discharge had almost completely disappeared, and within a week there was no urethral discharge, and the smear showed no organisms. The urine was clear. Slide smears from the urethra, November 15 and 21, and December 3 and 12 showed no gonococci. The urine was clear, with no shreds, and microscopically negative. The prostate was normal. He was seen again, January 17; he had remained well. Examination was negative.

Case 2.—*Gonococcus urethritis of two months' duration.*

J. A. B., a man, aged 25, admitted, June 15, 1929, had a urethral discharge of two months' duration. Examination showed purulent discharge with gonococci. The prostate was normal. Mercurochrome, 1 per cent, was given intravenously in two injections of 13 and 18 cc. at an interval of three days. There was no marked reaction. After the second injection there was no discharge; the urine showed no shreds and was microscopically negative. The patient received in addition acriflavine hydrochloride 1: 4,000, as anterior injections, and also potassium permanganate 1: 6,000. The patient was discharged apparently well on the twelfth day.

Case 3.—*Gonococcus urethritis of three months' duration.*

J. B., a man, aged 37, admitted, June 9, 1927, had urethritis of three months' duration. He had had gonorrhea fifteen years previously. Numerous gonococci were found on smear and culture. Mercurochrome 1 per cent was given intravenously three times, in 15, 18 and 20 cc. doses, with intervals of two and eight days. The urethral discharge became scanty, and gonococci were not found on the day after the first injection. Negative smears and cultures were made, June 13, 15 and 20. The patient was discharged, apparently well, June 20.

Case 4.—*Chronic gonococcus urethritis and prostatitis of four months' duration.*

R. C. H., a man, aged 37, admitted, March 2, 1929, had a discharge of four months' duration. He had had gonorrhea fifteen years before.. The discharge was not profuse; it contained a small number of gram-negative intracellular diplococci and gram-positive diplococci. Culture was negative for gonococci and positive for the gram-positive diplococcus. The diagnosis was subacute prostatitis and acute epididymitis. Urethral injections and intravenous injections of 1 per cent mercurochrome, in 12, 15 and 18 cc. doses were given with intervals of two and four days. There was improvement in the infection and rapid reduction in the size of the prostate. Slide smears from the urethra were negative, March 8, 9 and 13. The patient was discharged, March 14; there was no urethral discharge. Urine cultures were sterile; the prostate was small and slightly indurated. He returned four months later; there was no urethral discharge; the prostate was normal in size; the seminal vesicles were slightly indurated; the urine was clear, with no shreds, and cultures were sterile.

Case 5.—*Gonococcal urethritis, prostatitis.*

H. S. B., a man, aged 25, admitted, Feb. 4, 1925, had had urethritis for three months. There was a profuse urethral discharge. Gonococci were present. The prostate was enlarged, indurated and moderately tender. The prostatic secretion showed many pus cells. Urethral injections of meroxyl and strong silver protein were given. The urethritis persisted. Gonococci were present, February 21. He received intravenous mercurochrome, 1 per cent, twice, 14 cc. February 23, 19 cc. three days later. Following this he was entirely free from symptoms, except for an occasional mucoid urethral discharge, which contained no gonococci. March 5, the prostate was smaller than on admission. There were no urinary symptoms. No gonococci were found. There were a few shreds in the urine.

Case 6.—*Acute anterior gonococcus urethritis, superimposed on old prostatitis.*

J. H., a man, aged 23, admitted, Nov. 29, 1924, had had gonorrhea seven years before, and urethritis for one week. He had a pronounced urethral discharge; gonococci were present. Pus was found in the first glass of urine.. The prostate was slightly enlarged; the seminal vesicles were normal. Injections of mercurochrome, 1 per cent, intravenously, in 30, 30 and 20 cc. doses, were made during two weeks. There was no marked reaction. There was a prompt disappearance of gonococci. None were found in urethral smears, December 2, 6 and 13 or later. Local treatment with a number of drugs was given. The patient was followed for two months, during which prostatic massage was given for chronic prostatitis. Slide and cultures were negative for gonococci. He was discharged well.

Case 7.—*Gonococcus urethritis of seven months' duration. Old prostatitis and cystitis.*

W. E. O., admitted, Nov. 17, 1930, had had gonorrhea of three months' duration eight years before admission. He had a urethral discharge seven months before admission. Bilateral vasotomy and injection of seminal vesicles were done five months before. On admission the urethral discharge contained gonococci, which were also present in the urine and the prostatic secretion. Urethral injections were given and mercurochrome, 1 per cent intravenously, in 13, 15, 18 and 17 cc. doses over a period of two weeks. No urethral discharge and no gonococci were found, November 20, 21 and 26, and December 1. The prostatic secretion contained pus but no organisms. The reactions from the mercurochrome were slight. Urine cultures on discharge showed no gonococci.

Case 8.—*Acute anterior and posterior gonococcus urethritis and prostatitis.*

C. B. M., a man, aged 63, admitted, Sept. 20, 1929, with acute gonorrhea of two weeks' duration, had a profuse urethral discharge with numerous gonococci. The prostate was enlarged and very tender. The temperature ranged from 103 to 105 F. Urethral injections and intravenous injections of mercurochrome, 1 per cent, were given in 12, 15, 18 and 20 cc. doses in eleven days. The reactions were slight. After the third injection there was no urethral discharge. Urethral smears, October 9 and 11, were negative for gonococci, and the prostatic swelling was markedly diminished and less tender. At the end of six weeks, the patient, who had received prostatic massage, was discharged in excellent condition. The urine was clear, only a few shreds being found in the first glass. The prostate was markedly smaller. No gonococci were present. There was no urethral discharge. When the patient was seen six months later the urine was clear and free from infection. The prostatic secretion still contained leukocytes but no gonococci.

Case 9.—*Chronic prostatitis; acute gonococcus urethritis; prostatitis.*

L. R. B., a man, aged 31, admitted, May 9, 1929, had gonorrhea of five weeks' duration. There was a profuse urethral discharge; gonococci were numerous; cultures were positive. The prostate and the vesicles were involved. Urethral injections of mild silver protein and meroxyl were made. Three intravenous injections of 1 per cent mercurochrome were made in 13, 15 and 18 cc. doses in ten days. The reaction was slight. Gonococci disappeared after the first injection and did not return. Slide smears, May 16 and 24, were negative. Treatment for chronic prostatitis was begun and continued for three weeks with improvement. There was no return of the gonococci. He was discharged from the clinic, July 5. The prostatitis was markedly improved. No gonococci had been found on numerous examinations since May 11. Three months later an examination showed no recurrence.

Case 10.—*Acute gonococcus urethritis; epididymitis of three months' duration.*

W. B. S., a man, aged 45, was admitted, Nov. 19, 1928, with gonorrhea of six months' duration. The urethral discharge contained numerous gonococci on slide smear and culture. The right epididymis was enlarged and tender. The prostate and vesicles were apparently normal. Urethral injections were made; intravenous injections of mercurochrome, 1 per cent, in 8, 15, 15 and 20 cc. doses were given in seven days. There was only one pronounced reaction. November 23, a direct smear from the urethra showed no organisms. No gonococci and only a few gram-positive cocci were found on culture. During the next three weeks the patient received local treatment and on two examinations showed no gonococci. He was discharged, December 6; there was no urethral discharge; the prostatic secretion was sterile; the epididymis was "cleared up," and urination was normal.

Case 11.—*Acute gonococcus urethritis of four months' duration. Epididymitis, slight prostatitis and seminal vesiculitis.*

S. G., a man, aged 28, admitted, Oct. 9, 1925, was referred by a prominent urologist, who stated: "The patient has been under treatment for four months for very intractable neisserian infection." One month before he had developed epididymitis. There was a profuse urethral discharge; gonococci were present on examination. There was bilateral epididymitis, moderate and subacute. The prostate was slightly indurated and enlarged. The right seminal vesicle was slightly indurated. Local urethral injections were given. Three intravenous injections of mercurochrome, 1 per cent, 21 cc. each, were given within a week. There was very little reaction. There was however, a pronounced effect on infection. No gonococci were found after the second injection. The patient was examined at various times over a period of six months but showed no return of gonococcus infection.

Case 12.—*Acute gonococcus urethritis and epididymitis superimposed on chronic prostatitis.*

E. W., a man, aged 23, admitted, Dec. 20, 1927, with gonorrhea of five weeks' duration, had had gonorrhea three years before. There was a profuse urethral discharge with numerous gonococci and acute epididymitis. Urethral injections were given and mercurochrome, 1 per cent, intravenously, six injections, consisting of 15, 20, 20, 22, 20 and 15 cc. over a period of seven weeks. Gonococci were not found after the fourth injection, December 29. Treatment was continued for chronic prostatitis until Feb. 10, 1928. Numerous examinations showed no gonococci, but the prostatic secretion contained leukocytes. Cultures were negative.

Case 13.—*Acute gonococcus urethritis, prostatitis and arthritis.*

G. A. W., admitted, June 16, 1924, had had recurrent attacks of gonococcus urethritis for twenty years. He was brought into the hospital on a stretcher. He had arthritis of both knees. Both knee joints were acutely swollen. There was a profuse urethral discharge; gonococci were numerous. A culture of urine and prostatic secretion showed staphylococci. Urethral injections were given; mercurochrome 1 per cent, 28 cc., was given intravenously, July 24, and again, August 20. Three days after the first injection he had almost perfect function of the left knee, and the right was greatly improved. Cultures of the urine and the prostatic secretion were negative, July 26, 28, 31 and August 16. The patient was discharged, August 26, with complete function of both knees. There was no pain. There was no urethral discharge (slide cultures were negative), and the urine and prostatic secretions were normal.

Case 14.—*Acute gonococcus urethritis and arthritis.*

M. J. R., a man, aged 25, admitted, June 15, 1929, had had gonococcus urethritis for three months and arthritis for three weeks. Gonococci were present. There was a very acute tenosynovitis with reddening of the skin in the region of the left elbow. The prostate and vesicles were normal. Urethral injections were given and mercurochrome 1 per cent, intravenously in two injections of 20 cc. each, four days apart. On the day after the first injection there was a marked improvement of the arthritis. June 20 there was no urethral discharge, and the urine was negative. The arthritis was greatly improved. No gonococci were found. The patient returned two years later. There has been no recurrence of urethritis or arthritis. Examination was negative. The patient had developed a stone in the kidney, which was removed successfully at operation by Dr. Colston.

Complicated Acute and Chronic Gonorrhea.—A study of seventy-one cases of complicated acute and chronic gonorrhea, in which mercurochrome was administered intravenously, in addition to urethral injections, or irrigations, as previously stated, shows prompt disappearance of gonococcus infection and urethral discharge in forty cases, or 55 per cent. The effect is described as strikingly rapid in twenty-nine of these cases and excellent in eleven. In the other thirty-one cases the results of the intravenous therapy may be described as probably helpful in five cases, of doubtful value in eighteen cases, and of no effect in eight cases. In eighteen of these cases, however, the treatment was not as complete as we would have wished, generally because of the patient's failure to return. The cases that are included in this list of seventy-one cases comprise urethritis with prostatitis, sixteen cases; with prostatitis and vesiculitis, ten cases; with epididymitis, fourteen cases; with acute gonorrheal arthritis, twenty-four cases. In the twenty-four cases of gonorrheal arthritis we have evidence of the often great value of intravenous injections of mercurochrome in the quick amelioration of the joint condition in all cases, and the complete cure of the gonorrhea and its complications in fifteen cases. In nine cases, 39 per cent, intravenous injections of mercurochrome did not markedly hasten the result of treatment, and in three there was a complete failure.

Confirmation of our belief in the value of intravenous injections of mercurochrome in acute and chronic cases of gonococcus infection is to be found in a number of articles in the literature. Whitman,[2] after a study of a series of acute and chronic cases, says: "The rapid subsidence of symptoms in all, and the abrupt termination of symptoms in some cases was almost incredible to one accustomed to the usual slow methods of gonorrheal treatment." Potter[3] reported the results of intravenous injections of mercurochrome in twenty-four cases of acute gonorrheal urethritis, eight cases of chronic urethritis, eleven cases of acute gonorrheal prostatitis, six cases of gonorrheal epididymitis and seminal vesiculitis, and twenty-five cases of chronic prostatitis, from which he draws the following conclusions: "Mercurochrome-220 soluble is one of the most important new remedies for use in intravenous antiseptic medication. Acute rheumatism, synovitis, myalgia, neuritis, arthritis and other manifestations of absorption from the prostate and seminal vesicles, sites of local infection, will clear up rapidly on the intravenous administration of mercurochrome, as will also a large number of cases of gonorrheal urethritis, epididymitis, prostatitis and seminal vesiculitis." Walther,[4] in a report of 768 cases, said: "I am convinced that a large number of these patients were materially benefited by the dye intravenously, and that its employment appreciably shortened the duration of the infection." Williams and Small[5] report seventy cases of gonococcus infection treated with mercurochrome, together with sugar and foreign protein. Among these, twenty-two, or 31 per cent, were chronic gonorrheal infections, and ten, or 14 per cent, of the patients had had gonorrhea previously. The results obtained by the authors are stated to be: cases cured, thirty-nine, or 55 per cent, and cases apparently cured, but not followed as long as desirable, eleven, or 15 per cent. "Twenty cases were either improved or so recent that sufficient follow-up data are not yet available. All cases showed positive improvement. The average number of days between administration of mercurochrome and negative smears was 12.3 days. The almost immediate relief of pain is a striking characteristic, being particularly noted in the cases of acute epididymitis and cystitis."

Other reports on the use of mercurochrome intravenously in gonococcus infections are to be found in the literature, which has now become very voluminous, but we have mentioned these simply in confirmation of our steadfast belief in the great value of intravenous injections of mercurochrome as an aid in the treatment of both acute and chronic gonococcus infections and its complications. In practically all cases other treatment is necessary. We proved very early that intravenous injections of mercurochrome, or other drugs, did not cause a disappearance of organisms which were in the urethra, the lumen of which is not reached by the blood stream. In a series of cases in which no urethral injections were used, quick sterilization of the urethra was not obtained. By a combination of urethral injections to combat the gonococci in the urethra and chemotherapy to combat organisms which have penetrated deeply into the glands or tissues, a rational and often unusually effective method is presented for attacking this fearfully serious disease.

Infections of Urinary Tract Due to Bacteria Other than Gonococcus or Tubercle Bacilli.—As previously shown, a great variety of organisms are to be found as the infective agents in the lower and upper urinary passages, in the blood stream, and in organs secondarily invaded from the urinary tract. When these bacteria are localized to the bladder and urethra and are fairly acute in character, no great difficulty is experienced, as a rule, in getting rid of the infection, by means of simple antiseptic irrigations or injections, provided all obstruction to free urination is removed. Many such infections are self-limiting or autosterilizing by the simple natural processes. We not infrequently see cases after prostatectomy or vesical operation in which, under no treatment at all, the urine several months later is found to have become sterile. When, however, the process extends more deeply, involving the prostate and seminal vesicles, and particularly the renal cortex (pyelonephritis), it is rarely autosterilized. The cure of such pathologic processes is, indeed, not often obtained by local treatment (vesical or pelvic lavage). In some cases internal urinary antiseptics (methenamine, acriflavine hydrochloride, pyridium and caprokol) may be definitely helpful. Indeed, sometimes the alternate alkalization and acidifying of the urine may be peculiarly effective, but in many cases much more is necessary in order to accomplish results. It is here that intravenous chemotherapy and protein therapy promises much help.

The coccus infections have so far proved to be most easily eradicable by means of such methods; not infrequently many of the staphylococcus invasions of the kidney and bladder quickly disappear after intravenous injections of neoarsphenamine and also of mercurochrome. The following cases are given to show particularly the excellent results that may follow intravenous injections of neoarsphenamine:

Case 15.—*Chronic prostatitis and seminal vesiculitis. Staphylococcus albus infection of urine.*

W. S., admitted, Nov. 19, 1928, with a diagnosis of chronic prostatitis and seminal vesiculitis, and of staphylococcus infection of the urine, had had gonorrhea twenty-five years before, and again four years before. The urine on admission was infected with Staphylococcus albus. Injections were made into the bladder, and prostatic massage was instituted. Because of the persistence of the coccal infection, the patient received neoarsphenamine, 0.4 Gm. intravenously, December 4. The urine, which had been heavily infected the day before, was sterile the day after this treatment, and thereafter on December 8 and 19. The patient was discharged well, December 20.

Case 16.—*Congenital valve of posterior urethra, pyelitis of four years' duration. Staphylococci recovered from both kidneys.*

M. H., a boy, aged 6½ years, admitted, March 5, 1931, with pyelitis of four years' duration, had been treated internally. A congenital valve of the posterior urethra was discovered. The bladder urine was heavily infected with a staphylococcus, which was also found by ureteral catheter in both kidneys, March 10. On this date Dr. W. A. Frontz gave the patient 100 mg. of neoarsphenamine intravenously. The next day no organisms could be found in microscopic examinations of the urinary sediment, but there was a scant growth of the coccus after forty-eight hours of incubation. The urine two days later (March 13) was sterile.

Case 17.—*Acute bilateral pyelitis due to Staphylococcus aureus.*

L. L., a woman, admitted, January 13, had had urinary frequency and pain on voiding for eight days, pain in the region of the right kidney for five days, and pain in the region of the left kidney for one day. Cultures from the bladder and both kidneys by catheterization showed an atypical Staphylococcus aureus. January 14, Dr. W. A. Frontz gave the patient neoarsphenamine, 0.45 Gm. intravenously. The urine, January 15, showed very few cocci and the growth was very scant. January 19, the urine was sterile. The patient was examined several months later; the urine was sterile.

[5] Williams, L. H., and Small, W. D.: U. S. Nav. M. Bull. **25**: 621 (July) 1927.

Case 18.—*Staphylococcus; pyelitis and chronic prostatitis.*

N. H., admitted, Nov. 9, 1928, had had gonorrhea eleven years and epididymitis three years previously. The left kidney was removed eight months before because of stones. After that he had repeated attacks of pain on the right side. Cultures of the urine from the right kidney, November 20 and 23, showed Staphylococcus albus. November 24 the patient was given 0.45 Gm. of neoarsphenamine. Forty-eight hours later the urine from the right kidney was sterile. The patient was discharged December 1, with sterile urine.

Case 19.—*Chronic prostatitis; acute epididymitis; cystitis; urine cultures showing streptococcus.*

T. S., a man, aged 45, admitted, Dec. 21, 1930, had had hematuria, followed by epididymitis, ten months before. In September, a diagnosis of urethral stricture had been made and a sound passed. The patient entered the hospital with a right epididymitis. There was also a chronic prostatitis and purulent urine, the cultures showing a streptococcus. He received the following intravenous treatment: December 26, mercurochrome, 1 per cent, 12 cc., followed by a mild reaction, subjective improvement and slight softening of the epididymis. December 28, mercurochrome, 1 per cent, 15 cc., with no reaction. The epididymis became much softer and painless. January 1, 0.3 Gm. of neoarsphenamine was given. Epididymitis had subsided before this injection, which was given for the urinary infection. January 3, 0.3 Gm. of neoarsphenamine, and January 5, 0.45 Gm. of neoarsphenamine was given. January 7, 18 cc. of mercurochrome, 1 per cent, was given; the urine still showed coccus infection. January 9, urine cultures were sterile and continued so, but the patient was being treated for prostatitis by massage, and on January 14 a final injection of 14 cc. of mercurochrome, 1 per cent, intravenously was given. The patient was discharged January 24; the urine was sterile. The urine was again examined March 13; the cultures were sterile.

Bacillary Infections.—As shown before, the B. coli group form a large percentage of the bacteria found in infections of the bladder and kidney. Unfortunately, the bacilli are much more resistant to treatment than the cocci. In a good many cases the portal of entry is the intestinal tract, and much can be accomplished by colonic irrigations and other therapy directed to chronic infection of the gastro-intestinal tract. Internal antisepsis, as stated before, should always be tried and in some cases is distinctly effective. By alternating the drug and the method, occasionally surprisingly good results are obtained, but in the majority of cases a bacillary infection is very resistant to all forms of treatment. Local treatment, lavage of the bladder and renal pelvis with various antiseptics, is not infrequently successful, especially if alternation of drugs is carried out. For intravenous treatment one may use acriflavine hydrochloride, methenamine or mercurochrome. Each of these has been responsible for a certain number of fairly rapid sterilizations of the urine. That it is possible in some cases to get good results by the intravenous injection of mercurochrome, the following cases will show:

Case 20.—*Bilateral pyelonephritis due to B. coli-communior. Septicemia following ureteral catheterization. Condition of patient desperate.*

H. A. D., a man, aged 44, admitted, Dec. 30, 1922, had pain in the kidney which was shown on examination to be due to bilateral pyelonephritis due to B. coli-communior. The urine from both kidneys contained the infection but very little pus. Following catheterization the patient developed septicemia and grew rapidly worse, the temperature ranging from 102 to 104.6 F. Blood cultures showed 140 colonies of B. coli to 1 cc. of blood. The patient grew rapidly worse; he became irrational. Medical consultants thought the case hopeless and that the patient would not live more than a few hours. He was given 34 cc. of mercurochrome, 1 per cent, intravenously. This was followed by a chill, a rise of temperature to 103.8 F. and a drop of 6 degrees in four hours. Blood cultures twelve hours after injection were sterile and remained so. The next day the patient felt greatly improved; the urine became sterile, cultures were negative, and he was discharged from the hospital apparently well in seven days. He was seen repeatedly afterward. The urine remained sterile.

Case 21.—*Bilateral chronic pyelonephritis due to B. lactis-aerogenes.*

I. S. G., admitted, Jan. 2, 1923, had bilateral pyelonephritis shown by ureteral catheterization and cultures to be due to B. lactis-aerogenes. Pelvic lavage was done with silver nitrate, 1 per cent, and meroxyl, 1 per cent, unsuccessfully. January 12, mercurochrome, 1 per cent, was administered intravenously, 5 mg. per kilogram. The reaction was moderate. On the following day the urine was found to contain numerous bacilli (dead?), but cultures were sterile. Cultures on subsequent days showed urine still sterile and microscopically no bacteria were found.

Case 22.—*Child with double pyelonephritis due to B. coli. Very septic. Condition bad.*

M. L., a girl, aged 4 years (a Harriet Lane Clinic case), admitted, Nov. 2, 1923, with pain in the right side had a temperature of 102.5 F. and marked tenderness over both kidneys. The urine was very cloudy. Cultures showed B. coli. Leukocytes numbered 19,950. The temperature the next day was 105 F. The patient was very ill. One hundred milligrams of mercurochrome, 1 per cent, was injected intravenously. On the following day the temperature was 98. The patient was greatly improved. There was a slight recurrence of fever, and four additional intravenous injections of mercurochrome, 30 mg. each, were given. The temperature remained normal after the seventh day. The patient felt well, but the urine still contained bacilli.

Combined Coccus and Bacillary Infection.—In cases in which there is a combined coccus and bacillary infection we have frequently employed, with excellent results, neoarsphenamine to eradicate the coccus infection and then mercurochrome to combat the bacillary infection. The following case is one of this type.

Case 23.—*Bilateral pyelonephritis. Cultures of both bacilli and cocci.*

H. P. S., a man, aged 36, admitted, Jan. 12, 1923, had pain in the region of the kidneys, and hematuria. Ureteral catheterization showed pus cells and bacilli from both kidneys and cocci from the left kidney. Pelvic lavage was done intermittently without results until July 3, when he was given 0.3 Gm. of neoarsphenamine intravenously and ten days later another injection of 0.75 Gm. without reaction. Two days later cultures showed that the cocci had disappeared, but the bacilli were still present. July 13, the patient was given 30 cc. of mercurochrome, 1 per cent, intravenously, without reaction. Cultures, July 14, 16 and 17, were sterile. No organisms were found in the urine thereafter.

Fever.—Cases in which the presence of fever gives evidence of an infectious process somewhere may often be treated intravenously to advantage. In cases of prostatic hypertrophy, fever, coming on during the period of preparation, may be due to a periurethral, a periprostatic or a renal infection. The patient often becomes septic, with intermittent chills and fever without physical signs to indicate positively where the focus of infection lies. In such cases we have for a long time employed intravenous therapy with some excellent results. The following case is one of this type:

Case 24.—*Fever and marked evidence of sepsis following prostatectomy. Probable left pyelonephritis.*

J. B. B., a man, aged 61, was admitted, Feb. 26, 1925, with benign prostatic hypertrophy. The urine was infected with both cocci and bacilli. Perineal prostatectomy was done, March 2; convalescence was satisfactory until March 19, when the patient began to have a septic temperature. This continued with evidence of left pyelonephritis, and the patient received 18 cc. of mercurochrome, 1 per cent, intravenously. This was followed by a chill and drop in temperature to 97 F. The next day the temperature remained normal and stayed so. Swelling in the left kidney disappeared, and the patient was discharged, April 11.

Braasch and Bumpus[6] report the intravenous use of mercurochrome 118 times in eighty-two patients with urinary infections. Twenty cubic centimeters of a 1 per cent solution was found the most satisfactory. Reactions were seldom severe. They state that intravenous mercurochrome is particularly effective in acute and subacute infections of the urinary tract, and also of great value in acute general sepsis of various types. In thirty-six cases in which mercurochrome was given for acute pyelonephritis, in twenty-five the temperature returned immediately to normal by crisis and in eleven by lysis.

Septicemia of Urinary Origin.—In previous papers we have given in detail the results obtained by intravenous therapy with neoarsphenamine, gentian violet and mercurochrome in various types of septicemia. The results were not uniform, and while there have been many striking disappearances of the blood stream infection, there have been a goodly number of failures, particularly when some serious lesion, such as pulmonary embolism, remained an infecting focus, from which the infection of the blood continued to recur.

Blood stream infections are divisible into two groups: (1) the simple bacteremias, which are often transient and self-curing, and (2) true septicemias, in which the process is far more serious and usually not self-limiting. In such cases, strikingly good results may be obtained by chemotherapy unless there is an extensive pathologic process which cannot be reached. In previous papers we have presented a considerable number of cases of septicemia of all types of origin with successes and failures following intravenous therapy. We have not space here to discuss this big subject.

EXPERIMENTAL PROOF OF THE VALUE OF CHEMOTHERAPY

It seems remarkable after Ehrlich's great work with arsphenamine, his demonstration that relapsing fever and other tropical diseases could be cured by chemotherapy, and his prediction that in a few years many infectious diseases would be treated by chemotherapy, that so many of the medical profession should still remain hostile to chemotherapy.

In order to answer the objection that we had offered only clinical evidence of the value of chemotherapy, permission was obtained from Dr. Hugh S. Cumming of the U. S. Public Health Service to carry out an extensive series of animal experiments under the direction of Dr. George McCoy, director of the Hygienic Laboratory, in Washington, D. C. This work was done by Hill and Ellis[7] of the bacteriologic staff of the Brady Urological Institute. More than a thousand white mice were used. A pneumococcus strain of high virulence was chosen as the test organism. This pneumococcus was so virulent that the intraperitoneal injection of 0.5 cc. of a 1 : 1,000,000 dilution of a broth culture was invariably fatal within forty-eight hours. A series of 124 mice were treated with 0.3 cc. of a 1 : 1,000 dilution of mercurochrome after inoculation with from 33.3 to 1,000 lethal doses of culture. In spite of the high multiples of lethal doses used, 16 per cent of these animals were saved by mercurochrome alone. A similar series of animals, 440 in number, were inoculated as before with the same dilution of culture, and treated with 0.2 cc. of normal horse serum. As a result, 100 mice, or 22.7 per cent, lived. In an attempt to evaluate the action of mercurochrome when used in small, nongermicidal amounts, and in the presence of serum, a third series of mice were given combined treatment; i. e., 0.3 cc. of 1 : 1,000 mercurochrome and 0.2 cc. of normal horse serum. The inoculations paralleled those in the first two series. Of the 404 mice given the combined treatment, 173 animals, or 42.9 per cent, were saved. This mercurochrome-serum mixture exerted no direct killing action in vitro. It is therefore fallacious to conclude that, because high dilutions of drug in vitro are not active, no therapeutic action may be expected in vivo. The excellent results obtained in these experiments in protecting mice against many multiple lethal doses of pneumococci show clearly that under carefully controlled conditions very definite therapeutic action is obtained, in some cases even under extremely unfavorable conditions.

DOSAGE

Intravenous injections of neoarsphenamine had best be given according to the rules that are usually in force in the treatment of syphilis. In adults one should usually begin with an injection of 0.3 Gm. After an interval of about three or four days, 0.45 Gm. may be given, and then after a similar interval 0.6 Gm. Rarely have we found it desirable to use 0.9 Gm.

Mercurochrome is given intravenously in a 1 per cent solution, and in simple cases, such as gonorrheas and ordinary urinary infections, one should usually commence in adults with 12 cc. After an interval of two days, 15 cc. may be given, and after an interval of three or four days, 17 cc., and after like intervals, 18 and then 21 cc. Rarely is it necessary to go above the latter, although it may be desirable to give several doses of this amount. The interval both with neoarsphenamine and with mercurochrome depends somewhat on the reaction. Should there be a very pronounced reaction it might be desirable to delay a day or two more, or to switch over to another drug.

In coccus infections it is not a bad plan to alternate between neoarsphenamine and mercurochrome. In fulminating cases, such as grave septicemias, when there is no time to be lost, it is usually wise to use larger doses of mercurochrome, at least 3 or 4 mg. per kilogram of body weight, unless the patient is very fat. We have not had nearly as good results in which initial doses of 10 or 12 cc. of a 1 per cent solution of mercurochrome were used in septicemias, as when the initial dose was about 20 cc. The considerable increase in fever which usually comes on in such cases is probably an important factor in the good result that is obtained.

We wish to reassert most positively that these drugs may be used without fear of injury.

CONCLUSIONS

The bacteriology of the urinary tract shows an extremely varied flora and organisms of a wide range of virulence and susceptibility to antiseptics.

B. coli is inhibited by 1 : 500,000 mercuric chloride, whereas B. lactis-aerogenes is not inhibited until the strength of chloride in the broth culture reaches 1:30,000.

[7] Hill, Justina H., and Ellis, M. G.: Bull. Johns Hopkins Hosp. **44**: 40 (Jan.) 1929.

The alkalizing bacteria are best combated by acids.

The great difficulty of eradicating infections of the genito-urinary tract is due to the fact that the bacteria have usually penetrated deeply into the tissues and glands beyond the urinary passages. On this account, injections and irrigations frequently fail to eradicate the infection.

The use of chemotherapy and protein therapy have been shown to be of distinct value.

A series of complicated gonococcus infections the cure of which was greatly hastened by the use of intravenous mercurochrome, is cited as well as the failures.

Gram-positive coccus infections of the kidneys and bladder are shown by a series of cases to have been eradicated by intravenous injections of neoarsphenamine.

Bacillary infections of the urinary tract, particularly the Aerobacter group, have been shown to be especially resistant, but cases that have responded favorably to intravenous injections of mercurochrome are cited.

Septicemias of urinary origin and cases of sepsis without blood stream infection are shown in some instances to be much benefited by chemotherapy.

The authors reassert their confidence in the great advisability of supplementing local injections and irrigations in urinary infections with intravenous therapy.

ABSTRACT OF DISCUSSION

ON PAPERS OF DR. NESBIT AND OF DR. YOUNG, DR. COLSTON AND J. H. HILL

DR. T. C. STELLWAGEN, Philadelphia: I cannot help approaching this subject from the standpoint of the surgeon and the message the papers carried to me. We all realize that the really dangerous organism to the urologist is Bacillus coli. I feel that the colon bacillus carries with it a very definite mortality rate, of which we do not take sufficient cognizance. I believe the day is coming when in the postoperative management of the stone-bearing case, the prostatic case and the kidney case, the patient will be put on very definite preliminary treatment that will tend to eliminate the inroads of this infection. With that in mind, I have made it a point to attempt an immunization of these patients before any operative procedure. I am glad to see the charts presented by Young, Colston and Hill because I have always felt that we in Philadelphia have not had that beautiful factor of lack of infection in prostatic surgery. It does hold in kidney surgery, but not in prostatic surgery, and when we read the literature we are inclined to think that we have been, perhaps, negligent. The patients do have bacilluria, but many physicians tell us that their patients do not have this complication. I do not intend to pass any aspersion toward Dr. Peacock's technic, but I do feel that with this paper and with his results this clinches more definitely the necessity for postoperative drainage in bladder surgery. I feel that Dr. Nesbit is to be commemorated for his work. This had not been brought to us in a forcible manner before. I am in thorough accord with what he says in regard to staphylococcic infections of the kidney. I think many men have been entirely too radical in the surgical approach to these cases. I believe we resort to surgery too often, when common sense and a little tactful waiting will clear up these conditions We now can put this question of staphylococcus in carbuncle of the kidney. I have seen only three of these and in one the microscope did not reveal anything of particular significance. I was called in consultation in that case with a homeopath. I think none of us would have gone in, but he had courage, and he found a carbuncle of the kidney. I would have let the case run on for a week or ten days longer. Another question I wish to mention is the "blow up" of the prostatic patient about ten to fifteen days after operation. He goes to the necropsy table and his kidney is found to be literally shot with punctate cortical abscesses. These are staphylococcic, and I think they are one of the important problems we have to consider.

DR. EDWARD L. MERRITT, Fall River, Mass.: Some years ago I took up the cystoscopic method of freeing kidney and ureteral stones and it was so successful that I wondered why we could not clear up kidney infections by the same method. Although many of them were of colon bacillus origin, I found I was successful in clearing them up by ureteral dilation and by kidney lavage through the cystoscope and ureteral catheter. Following this I saw three cases of staphylococcic infection of the kidney following some sinus infection as a complication of influenza. These were mild and cleared up under conservative treatment, such as Dr. Nesbit outlined. Last year this small series was increased by a case that I reported before the New England branch of the American Urological Association. That case was regarded as wellnigh hopeless. The patient, a boy, aged 15 years, had an infection of the left kidney, with a high temperature and leukocytosis. By cystoscopic treatment using a heavy ureteral catheter, I was successful in breaking through from the kidney pelvis, and a pure culture of Staphylococcus aureus was secured from this kidney. That kidney was irrigated thoroughly, with excellent results. I think it makes no difference what antiseptic is used, so long as one takes the lid off. The main thing in these cases, as is other infections, is to secure drainage, and if this is successfully done a great deal can be accomplished. This patient recovered spontaneously following thorough drainage.

DR. MEREDITH F. CAMPBELL, New York: Dr. Nesbit said that carbuncles of the kidney are rare. I wish to show a specimen of a rather unique and clinically interesting case. A child was admitted to the hospital at the age of 3 weeks, with furunculosis from head to foot. At the age of 7 weeks, a kidney abscess opened and drained. The child did well for a few days, when the temperature rose to 102 F. and then rapidly declined. At 11 weeks of age, no other pathologic changes being found, the kidney was explored and it was deemed wise to remove it.

DR. BUDD C. CORBUS, Chicago: During the past few years there has been a continuous search for new antiseptics with which to combat infection. While the results at times have been fairly satisfactory we are still a long way from the ideal method of treating infections of the genito-urinary tract. Antiseptics may kill bacteria in a test tube but their action in infected tissue is entirely different. Besredka has stimulated new ideas in immunization by his publications on antivirus. He has called attention to the fact that bacteria, when growing in a liquid culture medium, produce a toxin that is capable, when applied locally or injected intradermally, of producing both local and general immunity. The possibility of using the skin as an organ of immunization is being recognized more and more. It seems probable that in the near future either bacteria or their toxins will be used in the production in the skin of immune substances capable of protecting the body against specific infections.

DR. J. DELLINGER BARNEY, Boston: I think the diagnosis, especially of the mild cases, is one of extreme difficulty and they are put down as everything but cortical abscesses of the kidney, and are often operated on. They are often bilateral, or if not so in the beginning they may become so, and that is a reason for conservatism. Radical surgery, consisting generally of nephrectomy, formerly was the custom. Recently it has been found that one can be very conservative in their handling. Many patients who were very ill have recovered under conservative treatment and watchful waiting, and I have no doubt that the results would be the same as those found at operation in other cases. Many cases in which this condition is not suspected are seen at necropsy. I have seen them after prostatectomy, for example, at necropsy when there were multiple cortical abscesses which had not been suspected at all. All this makes me believe that the adhesions seen in operating on kidneys for other conditions are often due to mild attacks of this nature.

DR. VINCENT VERMOOTEN, New Taven, Conn.: I wish to offer for consideration one point, that is, the examination of the urine by studying a stained smear of freshly obtained urine. A number of years ago, I found that in 33 per cent of instances the cultural report was entirely different from the observations made from the stained sediment of the urine. This seemed so incredible that Justina H. Hill of Baltimore took up the question also and examined 3,000 specimens of urine in this way and took cultures of them. She got the same results that I did. Organisms seen in the smear did not grow out on culture and vice versa. Nesbit, in some instances, found the staphylococcus in the urine without any pus cells; the absence of pus cells was responsible for the fact that on the preliminary examination this was overlooked. In two cases of septicemia I have been able to find organisms with no pus cells in the urine, once the streptococcus and once the staphylococcus. Blood cultures taken at the same time showed, twenty-four hours later, that these patients had a blood stream infection. I think the fact should be emphasized that the stained sediment of a specimen of urine may give indications of a positive blood stream infection before it is possible to obtain blood cultures. In some cases, this will hasten the diagnosis.

Dr. W. F. Braasch, Rochester, Minn.: I wish to call attention briefly to a group of acute infections of the kidney which are not necessarily hematogenous in origin, although I dare say that at times they are. I refer to acute infections of the kidney following instrumentation or manipulation. This may occur with manipulation of either the lower or the upper urinary tract. When it occurs with the latter, the infection is usually ascending. It is observed occasionally following manipulation for stone in the ureter or the passage of a catheter for hydronephrosis. The acute cortical infections that result should be treated quite contrary to the method suggested by Dr. Nesbit. They are usually unilateral at least primarily, but if nephrectomy is delayed the other kidney becomes involved. They are always surgical and the sooner the kidney is removed the better is the prognosis. After the first day or two the symptoms may assume the form of a profound toxemia rather than the usual evidence of acute infection. One cannot be too careful in recognizing these cases and in advising immediate nephrectomy. If delay is permitted, the other kidney becomes infected and the patient may succumb.

Dr. George R. Livermore, Memphis, Tenn.: Along the line Dr. Braasch has suggested, the intravenous use of methenamine is an aid. We make it a rule in all ureteral manipulations to use methenamine intravenously, in doses of 30 grains (2 Gm.). This will mitigate and in time prevent these infections. If the theory of Dr. Corbus is correct, why not use both of these methods?

Dr. J. A. C. Colston, Baltimore: I should like to say a few words about the method we employ in cases of colon bacillus bacteremia. It might be well to state briefly two cases which illustrate certain points. A man, aged 62, with sterile urine before operation, was subjected to perineal prostatectomy without preliminary catheter drainage. Four days after operation a severe chill occurred and a blood culture showed an overwhelming colon bacillus infection. The usual supportive measures, together with intravenous administration of dextrose, were used, but the infection persisted with a septic temperature and the patient died ten days after operation, the blood culture just before death still showing an overwhelming colon bacillus infection. Such a patient we should now treat by intravenous administration of mercurochrome-220 soluble. We do not feel that mercurochrome could possibly sterilize the blood stream, as laboratory experiments have been carried out in the Brady Clinic which have proved that this is impossible. However, we feel that the intravenous use of mercurochrome produces some sort of protective reaction on the part of the body, which reaction plays a most important part in combating blood stream infections. The degree and the severity of this reaction can be largely regulated by the size of the dose. Of its nature, we know nothing. I was interested to hear Dr. Corbus attribute these reactions to the spleen. The second case was that of an elderly woman with a stone in the kidney and a severe urinary infection. Following pyelography she had a severe reaction with chills and fever, and a blood culture showed a very heavy colon bacillus infection. She was given mercurochrome, which produced a moderately severe reaction and a day later the blood culture was negative. However, shortly after this the blood culture again became positive, with chills and fever. Mercurochrome was again given and the culture became sterile. This sequence of events happened a third time, and we began to realize that she was reinfecting herself from some focus. A roentgenogram was then taken which showed that the stone had descended into the lower part of the ureter. The stone was then removed by operation, but the patient's vitality had been so sapped that she was unable to rally. The case was particularly interesting in that on three separate occasions blood stream infection was eliminated by intravenous administration of mercurochrome and I have always felt that if the descent of the stone had been recognized earlier this patient might have been saved.

RESULTS IN CHOLECYSTECTOMY

WITH ESPECIAL REFERENCE TO THE SYMPTOMATOLOGY AND DIAGNOSIS OF CHOLECYSTITIS *

M. F. DWYER, M.D.
AND
G. A. DOWLING, M.D.
SEATTLE

Chronic diseases of the gallbladder and bile ducts are at present generally conceded to be the most frequent organic cause of dyspepsia. No chapter in modern medicine is more interesting than the one dealing with the rapid advancement in the recognition of the gallbladder as a cause of gastric symptoms. If one consults the textbooks and reviews the literature of little more than a decade ago, one finds the gallbladder held responsible only for the illness of those patients who suffered recurrent attacks of biliary colic.

The rapid advance in knowledge of gallbladder disease is due almost entirely to the clinician's careful study of the symptomatology, aided to a great extent by the roentgenologist's ability to rule out organic changes in the stomach and duodenum and, of late years, by cholecystography.

In a recent study [1] of 3,000 patients complaining of gastric symptoms, the gallbladder and bile ducts were considered responsible for the symptoms in 21.3 per cent of the series. The approximate relative frequency of abdominal organic disease causing dyspepsia was gastric ulcer 1, gastric cancer 2, duodenal ulcer 5, gallbladder disease 11. That one out of every five patients complaining of gastric symptoms receives a diagnosis of chronic cholecystitis is a relatively constant finding. During the past ten years, our figures relative to this statement have not varied by as much as 2 per cent.

Owing to the fact that disease of the gallbladder is such a comparatively common diagnosis and since nearly one half of the patients receiving such a diagnosis are advised to have their gallbladders removed, we considered it well worth while to ask those patients on whom we had performed cholecystectomies how much benefit they considered they had received from the removal of the gallbladder. Before discussing the results of this investigation, we made a review of the case histories of patients receiving a primary diagnosis of cholecystitis in order to obtain a general idea of the symptomatology and clinical evidence on which the diagnosis of chronic cholecystitis was made. A summary of the observations is here presented. Six hundred histories out of a series of approximately 1,500 diag-

[1] Dwyer, M. F., and Blackford, J. M.: Interpretation of Gastric Symptoms: Clinical and Roentgenological Study of Three Thousand Cases, Radiology **14:** 38 (Jan.) 1930.

noses of chronic gallbladder disease were studied in detail.

Diseases of the gallbladder were diagnosed 395 times in females and 205 times in males, the ratio of incidence, therefore, between females and males being approximately 2 to 1.

The familiar saying that gallbladder disease is a disease characteristic of fat females over 40 years of age is true in the majority of instances, but, as knowledge of gallbladder disease increases, this statement loses considerably in weight. The review of these histories showed that 35 per cent of the patients were under the age of 40 and that 43 per cent of the females weighed less than 140 pounds (63.5 Kg.).

Table 1.—*Comparison of Age of Patients at Onset of Symptoms*

Diagnosis	Percentage		
	Seeking Relief Before Age of	Dating Symptoms Before Ages of	
	45	25	20
Cholecystitis	78	23	9
Duodenal ulcer	66	56	15
Gastric ulcer	36	25	4

In comparing the histories of patients suffering from duodenal ulcer and chronic cholecystitis, it is interesting to note that 50 per cent of our patients with duodenal ulcer stated that the onset of their gastric symptoms began before the age of 25, while only 22 per cent of patients with disease of the gallbladder began to have symptoms before 25 years of age (table 1).

Not many years ago, pain was considered a cardinal symptom of disease of the biliary tract, and many clinicians hesitated before arriving at a diagnosis of gallbladder disease without this as the chief symptom. Dyspepsia has been emphasized of late by various writers as a prominent complaint. Approximately three fourths (72.7 per cent) of the patients in this series sought relief on account of chronic gastric disturbances, and in over half of these the gastric symptoms had persisted for more than ten years. Localized pain or soreness of varying degrees is a common complaint, but only 18.5 per cent gave a history simulating that of one or more attacks of "gallstone" colic.

Table 2.—*Gastric Analyses of Four Hundred and Two Patients Receiving a Diagnosis of Chronic Cholecystitis*

Free Hydrochloric Acid	Number	Percentage	
Absent	98	24.4	55.7
Low (0-20)	126	31.3	
Medium (20-40)	151	37.5	
High (over 40)	27	6.7	

The gastric analysis was recorded in 402 cases. In 55.7 per cent of these examinations, the analysis of the gastric contents showed either the absence of free hydrochloric acid or the presence of a low acidity. In only 6.7 per cent was the free hydrochloric acid above normal. The clinician should hesitate before making a diagnosis of chronic cholecystitis on a patient presenting a history of chronic indigestion in the presence of a hyperacidity (table 2).

The roentgenologist has for many years rendered considerable assistance to clinicians in the diagnosis of chronic cholecystitis. The roentgen evidence of gallbladder disease before the advent of cholecystography consisted chiefly of the demonstration of gallstones on the roentgenogram and of the indirect signs manifested by changes in the contour, position and behavior of the duodenum and pylorus. The degree of accuracy and the value of these observations varied considerably with different roentgenologists.

Before Graham and his associates described a method of examining the function of the gallbladder objectively, we believe that the roentgenologist's chief assistance in the diagnosis of disease of the biliary tract came from the elimination of organic disease of the stomach and duodenum as a possible cause for the dyspepsia.

Four hundred and thirty-two patients in the series had routine roentgenologic examinations of the stomach and duodenum. In 405, or 93.5 per cent, the results of this examination were considered negative. Of the remaining 28 cases, 23 were reported as showing organic disease of the stomach or duodenum. We realize that occasionally a distended gallbladder or extensive adhesions from the gallbladder to the duodenum may cause deformity of the contour of the duodenum or pylorus, but such observations in this series were very infrequent. In 93.5 per cent of the patients examined there was no roentgenologic evidence of abnormalities of the duodenum or pylorus that could be attributed to a distended gallbladder or to adhesions.

Cholecystography has been a great contribution to the chapter on cholecystitis, and the profession is greatly indebted to Graham and his associates for furnishing a method of [illegible]ction of the gallbladder objectively. [illegible] is undoubtedly the best single laboratory test, but it should never be relied on to the exclusion of other data to affirm or deny the presence of disease of the gallbladder. The intravenous method of administering the dye has been used exclusively by us for the past five years. Positive roentgenologic evidence of impaired gallbladder function, such as absence or faint concentration, is strong presumptive evidence of disease of the gallbladder, and this has been found to be true in over 90 per cent of our proved cases. Negative cholecystographic evidence in the presence of good clinical history of gallbladder disease and negative roentgenologic examination of the stomach and duodenum should never deter the clinician from arriving at a diagnosis of chronic cholecystitis. The cholecystograms were considered negative in 21 per cent of patients receiving a clinical diagnosis of disease of the biliary tract. Occasionally it is found that the gallbladder of a nervous, temperamental patient, presenting an indefinite group of abdominal symptoms, fails to cast a shadow after the administration of the dye. Such patients, after a few weeks of medical supervision and encouragement, often show on reexamination a well functioning gallbladder, which emphasizes the fact that cholecystography is a test chiefly of function rather than of disease.

Questionnaires were sent to approximately 300 people who had received surgical treatment for chronic disease of the gallbladder. All these patients were examined by the same clinicians and the same roentgenologist and were operated on by one surgeon. One hundred and fifty-three patients responded to the questionnaire, and these form the basis of this study. We realize that patients are often confused in making out such reports, and therefore we tried as much as possible to ask only a few general questions and to frame these questions in as simple a manner as possible.

These people were asked to answer the following questions: 1. Had they obtained complete relief from the symptoms for which the operation had been performed? 2. If they considered that they had not obtained complete relief, did they consider themselves 75 per cent, 50 per cent or 25 per cent benefited, or had they not received any benefit at all from the operation? 3. Had there been any improvement in their digestive disturbances and if so to what extent? 4. Had they had recurrence of colic? 5. What effect had the operation had on gas and belching? 6. Were they now able to eat certain foods that they could not eat before operation? Each questionnaire was filled out independently by the patient, and no aid or suggestions were given by a physician. The figures here presented are exactly as given by the 153 patients and are based on their own opinions as to the extent of relief derived from the operation.

In reply to questions 1 and 2, regarding the relief of symptoms, obtained by cholecystectomy, 56.2 per cent stated that they had obtained complete relief and 23.5 per cent considered that the operation had relieved 75 per cent or more of their previous complaints. One fifth of the patients in this series (20.3 per cent) answered that they believed that the operation failed to produce the results they had hoped for, as they considered that only one half or less of their symptoms had been relieved by the removal of their gallbladder. Any operative procedure that eliminates the symptoms of 75 per cent or more of a chronic ailment may be considered conservatively in the group of good results, and 79.7 per cent of these patients considered that their operation was a cure for the symptoms for which they sought relief. Other diseased organs besides the gallbladder were removed in some cases, and this may to a certain extent have influenced favorably the end-results in these instances; however, in checking over the surgical records of these patients, we were surprised to find that diseased organs other than the gallbladder had been noted in only thirty-six patients (table 3).

Table 3.—*Relief of Symptoms Following Cholecystectomy*

Degree of Relief	Number	Percentage	
Complete	86	56.2	79.7
75 per cent	36	23.5	
50 per cent	15	9.8	
25 per cent	9	5.7	
None	7	4.5	
Total, 153			

The records of the 20.3 per cent of patients who replied that they had received 50 per cent or less relief of their symptoms following the removal of the gallbladder were carefully studied in order to determine if possible the reason for the failure to obtain more favorable results. The surgical observations on these thirty-one patients showed that the gallbladders of fifteen were definitely diseased, and in ten of these there were stones. Four gallbladders were considered doubtful at operation, but on account of the clinical observations and in the absence of other pathologic evidence they were removed. Among the remaining twelve patients, three had received a preoperative clinical and roentgenologic diagnosis of duodenal ulcer. The surgeon reported that in these three patients no ulcers were demonstrated but that two had a diverticulum of the duodenum and the third a probable duodenitis. A retrocecal appendix was found in eight patients, and in the remaining case no pathologic changes except the scar of a gastric ulcer could be demonstrated.

Table 4.—*Condition of Digestion Following Cholecystectomy*

	Number	Percentage
Much improved	105	70.5
Partially improved	25	16.7
Not benefited	17	11.4
Worse	2	1.3
Total, 149		

Table 5.—*Condition of Gas and Belching Following Cholecystectomy*

	Number	Percentage	
Absent	56	37.8	80.3
Better	64	42.5	
Same	21	14.3	
Worse	7	4.7	
Total, 148			

Seven patients answered that they had received no benefit at all following their operation. The gallbladder in three cases was found markedly diseased, in each case there were stones, and in one of these three cases a subacutely inflamed appendix was also removed. In two cases the gallbladder was described as showing slight evidence of disease, and an apparently normal gallbladder was removed in another patient who subsequently had been classed by several clinicians as a profound neurasthenic. The seventh patient in the group received a clinical and roentgen diagnosis of duodenal ulcer and a surgical diagnosis of duodenitis.

Dyspepsia brings more patients with diseases of the gallbladder to the physician than any other complaint; consequently, the degree of relief of this condition is a fair index as to the benefit derived from the removal of the gallbladder. In answer to the question regarding this condition, 70.5 per cent stated that their digestive disturbances were greatly relieved, 16.7 per cent partially improved, 11.4 per cent not benefited, and two patients, or 1.3 per cent, stated that their digestion was worse following operation (table 4).

Table 6.—*Effect of Cholecystectomy on Food Selection*

	Number	Percentage
Better	94	68.1
Same	42	30.4
Worse	2	1.5
Total, 138		

Gas and belching are common and annoying complaints of most people with diseased gallbladders. These symptoms after operation were either absent (37.8 per cent) or markedly relieved (42.5 per cent) in 80.3 per cent; no change was noted in 14.3 per cent, and 4.7 per cent stated that they considered themselves worse following the operation. The continued absence of free hydrochloric acid in the gastric contents is the cause of the failure of some patients to receive much relief of their digestive disturbances following cholecystectomy (table 5).

Food selection is a frequent complaint. The foods most commonly avoided are rich and highly seasoned foods, fried meats, fats and raw apples. In answer to the question as to whether or not the removal of the gallbladder permitted these patients to eat without distress certain foods that they could not eat before operation, 68 per cent replied in the affirmative. Many patients were very emphatic in their statements relative to this question, affirming that they could now enjoy many foods which previously would have caused them great distress. Thirty per cent stated that they noticed no particular difference following the operation, and only two out of the forty patients who were not benefited stated that they considered that they had to be more careful regarding the selection of food after the removal of the gallbladder (table 6).

Colic is a common symptom in patients with diseases of the biliary tract and is complained of by many in whom it is found at operation that the gallbladder and bile ducts do not contain stones. The exact cause of gallbladder and duct colic not due to calculi has not yet been definitely established. In this series, 11.8 per cent of the patients reported having had one or more spells of colic after the operation. The majority of these attacks, however, occurred in the first few years following the removal of the gallbladder, and in many of these the gallbladder and ducts did not contain stones, as only 45 per cent of the total series were found at operation to have stones.

SUMMARY

1. Chronic cholecystitis is the most frequent cause of gastric symptoms. The diagnosis of this condition by the correlation of clinical, roentgenologic and laboratory observations has reached a high degree of accuracy.

2. Nearly one half (42 per cent) of our patients receiving a diagnosis of chronic disease of the gallbladder are considered surgical patients at the time the diagnosis is made. That the removal of the gallbladder of these patients is a satisfactory procedure is manifested by the fact that 79.7 per cent state that they consider the operation a cure for the symptoms for which they sought relief.

3. The avoidance of certain foods is a common complaint of patients with diseases of the biliary tract. Sixty-eight per cent of the patients in this series stated that after the removal of the gallbladder they could eat without discomfort certain foods which before the operation caused them great distress.

4. Symptoms of dyspepsia, especially gas and belching, were either entirely relieved or greatly benefited in 80.3 per cent of the cases in which operation was performed.

5. The surgeon should not be hasty in deciding against removal of the gallbladder because of its normal external appearance if he knows that disease of the gallbladder was diagnosed only after careful clinical, roentgenologic and laboratory examinations. Lack of the appearance of gross pathologic changes of the gallbladder in situ fails to outweigh careful clinical and laboratory deductions, and failure to remove the gallbladder in such instances is generally followed by a continuation of the symptoms for which relief was sought.

ABSTRACT OF DISCUSSION

DR. WILLIAM H. STEWART, New York: There are a certain number of cases in which it is difficult to explain why the opaque bile does not enter the gallbladder or, if it does, why there is "no shadow." Defective technic will clear away a few of them, but there remain a number in which one wonders whether there is not some chemical change in the dye after it enters the gallbladder that breaks up the iodine compound and renders the bile nonopaque. One German observer claims that as the result of the inflammation the absorption of the watery bile before concentration has occurred is so rapid that the bile does not become opaque. Lahey and Jordan, who use the intravenous technic, state that in 44 per cent of sixty-five cases of functional or spastic irritability the cholecystographic test gave a "no shadow" but that after five or ten days of bowel management the gallbladder filled normally. I believe that in these irritable spasmodic colon cases there is an associated spasm of the cystic duct, so that none of the opaque bile enters the gallbladder. When the irritation is removed, the bile again enters in a normal manner. If this is true, the obstruction might be classed as functional. The authors of the paper report 21 per cent of negative cholecystographic observations with clinical disease of the biliary tract. This is considerably higher than mine. With the oral method I expect about 15 per cent. It is, however, safe to say that it is very unusual in institutions with which I am connected for the surgeon to operate when the cholecystographic observations are negative. The authors are to be congratulated on the study that they have made in these cases, and particularly on the follow up. After all, the result of surgery of the biliary tract is the important question. Drs. Dwyer and Dowling have shown that in their cases it was well worth while.

DR. JOHN F. HERRICK, Ottumwa, Iowa: It has been my observation that a large percentage of those who complain of trouble in the right upper quadrant are not suffering exclusively from disease of the gallbladder, but in many cases there is a hepatitis. There is at present a discussion as to whether hepatitis or cholecystitis is primary. The general opinion, especially among surgeons, has been that hepatitis is a result of chronic infection of the gallbladder. My feeling is that the primary disease in the average gallbladder case is infection and dysfunction of the liver. If that is true, we are starting at the wrong end and working backward. If the primary disease is infection and dysfunction of the liver with faulty bile secretion, it is easy to understand how cholecystitis would result with all the manifestations that follow. The authors are unusually fortunate in the number of cases relieved by cholecystectomy, because my observation has been somewhat different: The percentage of cases relieved has been considerably lower and many of the patients have complained afterward that they were sorry they had the operation. If one goes back and traces the physiology of digestion with the excess of carbohydrates that we as a people are using and recalls that the liver must convert the carbohydrate into glycogen, it is apparent that the liver may find itself in the position of our agricultural board. It has its elevators all stocked and no place to dispose of the product. The consequence is hepatitis, dysfunction of the liver with defective bile secretion opening the way for inflammation of the gallbladder, secondary to the primary cause, which is this functional liver disturbance. If the radiologist will assist the internist in explaining those cases, he will do valuable work and will establish himself more and more as a consultant.

DR. MAURICE F. DWYER, Seattle: I agree with Dr. Stewart. He has added much to our paper. It is generally agreed that, owing to the lymphatic anastomosis between the liver and the gallbladder, chronic cholecystitis is associated with hepatitis, and also that the infection may spread by the venous route, as the cystic vein draining the gallbladder empties directly into the portal vein. However, some surgeons of large experience state that the so-called objective markings of the liver commonly described as hepatitis are seen more frequently at operation than the so-called normal liver. The physiology of the liver and bile ducts is interesting. There is a lot of work being done at present on the detoxifying power of the liver. Occasionally, at operation, the surgeon finds a gallbladder which objectively looks normal, although the clinical aspects of the case strongly suggest a diseased gallbladder, and discovers that the removal of the gallbladder is followed by the elimination of the symptoms for which the patient sought relief. Whether the removal of the gallbladder establishes adequate drainage of the detoxified liver or not is still open to further investigation. The review showed that 80 per cent of the patients who had the gallbladder removed considered the operation a success. We have also sent out questionnaires to an entirely different group; namely, those in whom we diagnosed chronic gallbladder disease and advised operation between five and fifteen years ago, but who for some reason or other refused operation. We were interested in knowing what became of these patients. All questionable diagnoses were eliminated, and we considered only those histories which, from the clinical and roentgen evidence, seemed to indicate with reasonable certainty an infected gallbladder. The summary of this investigation was that one third of the patients treated medically came to operation from three to five years after the diagnosis was made; one third, because of continuation of their symptoms, should have come to operation, and one third were relieved of their symptoms. Patients who have allowed their gallbladder symptoms to go on for a number of years and whose gastric acidity has become low or absent, with definite or permanent pathologic changes in the liver, cannot expect to get as good results following cholecystectomy as those who come to early operation. Ability to eat all kinds of food is 30 per cent more likely to be obtained from early operation than from either late operation or medical treatment. There may be a lot of truth in the saying that "an apple a day keeps the doctor away," but an apple a day eaten by a patient with an infected gallbladder often causes the doctor to come a-running; it is surprising to note the number of people with chronic gallbladder disease who cannot eat a raw apple without great distress.

PRACTICAL POINTS IN OPHTHALMIC PRACTICE

A STUDY OF RECENT FOOD RESEARCHES *

LAURA A. LANE, M.D.
MINNEAPOLIS

Since early times, the existence of a relationship between diet and certain diseases of the eye has been recognized. Early Egyptian literature tells of people living on special diets, seeing poorly at twilight, and the cure of this hemeralopia by the feeding of liver.

Egypt was the greatest grain raising country of antiquity. Grass grazing land, cattle and dairy products were scarce. These conditions have continued and may be responsible for much of the eye disease existing in Egypt today.

EFFECT OF FAULTY DIET ON THE EYE

Chow[1] states that one of the most constant signs of a food deficiency is a pigmentation of the conjunctiva with reduction of the light sense to half normal or less and that 65 per cent show the reduction without signs of an avitaminosis as Bitot spots or prexerosis of the cornea. Ejler Holm[2] has shown that the retina is rich in vitamin A. An avitaminosis may cause an increase of lipoids in the outer segment of rods and a decrease of the visual purple. An excess of carbohydrates may cause serious eye disease. Shoemaker[3] and Sinskey, Levin and Sachs[4] cite cases of episcleritis completely controlled by the withdrawal of excessive carbohydrates and the resuming of a proper diet.

Reeder[5] and others call attention to retinochoroiditis developing in persons on high carbohydrate diets. Cloudy vitreous and other symptoms improve on correcting the diet.

G. M. Findlay[6] reports an outbreak of conjunctivitis and atypical pneumonia in a school near Edinburgh. Similar outbreaks had occurred; no form of treatment relieved the conjunctivitis. The food, in order to save expense, was prepared in large caldrons and boiled from three to four hours, destroying the vitamins. Findlay recommended raw swede juice and cod liver oil; the outbreaks ceased.

Merz-Weigand,[7] Gonzelas[8] and certain Japanese writers report extensive outbreaks of hemeralopia due to dietary deficiencies. In addition to lack of fat soluble A the prolonged lack of green foodstuffs and other essentials together with the increased stimulation of sunlight on a depleted retina cause this hemeralopia to occur in the springtime.

Blegvad, Bloch, Mori, Pillat, Ross, Widmark, Wright and others have called attention to xerophthalmia and keratomalacia with damage to vision and their relation to the lack of fat soluble A.

Eye changes in diabetes considered due to rapid withdrawal of carbohydrates and salts may as likely be due to the lack of calcium and other elements in long continued faulty diets producing changes in the vessel walls and chemical changes in the blood. Ophthalmologists see hemorrhages in diabetic patients at other times than when rapid withdrawal of carbohydrates and salt is made.

Retinitis pigmentosa is hereditary in about 35 per cent of the cases. Trantas[9] and others suggest the feeding of liver in this disease. Trantas says that hemeralopia and keratomalacia not too far advanced will disappear in from two to seven days with liver feeding, while cod liver oil cures in from two to twelve weeks.

COMPOSITION OF THE BODY AND OF FOODSTUFFS

The elements found in the human body are oxygen, carbon, hydrogen, calcium, phosphorus, potassium, sulphur, sodium, chlorine, magnesium, iron, iodine, aluminum, arsenic, boron, cobalt, copper, fluorine, manganese, silicon and zinc. Constant disintegration and constant metabolism go on. The body eliminates daily more or less of each of the elements. To maintain life, health and high efficiency, the daily losses of these elements must be replaced. Replacement is through the foods ingested.

CONSTITUENTS OF FOODSTUFFS

Foodstuffs are divided into (1) proteins, (2) carbohydrates, (3) fats, (4) essential mineral elements and (5) vitamins. Proteins furnish but five of the elements making up the body; carbohydrates and fats only three of these five. The remaining seventeen must be derived from other ingredients of the food intake; namely, from the ash or mineral elements.

PROTEINS

Proteins replace soft tissue losses and occur in plant and animal life. Protein[10] is necessary to life. Sherman[11] states that more than fifty have been isolated. Proteins are complex, and corresponding tissues of different species are not identical substances. Certain radicals (amino-acids), tryptophan, lysine, cystine, hystidine, phenylalanine, proline, glycine and alanine are essential.

Quality of Protein.—Vegetable protein is not as good in quality as animal protein; both are needed for nutrition. Clayton[12] has shown that the protein of liver is of high value; kidney ranks next, then beef. Proteins of poor quality and lack of vitamin A will produce xerophthalmia more quickly than proteins of high quality.

Sources of Proteins.—Proteins are most abundant in cereals, beans, peas and nuts in vegetable life, and in meats, eggs, milk and fish in animal life. Nelson[13] says that vitamin B mitigates the ill effects of high protein diets.

How much protein is necessary? From 60 to 75 Gm. daily is usually sufficient; however, 100 Gm. may be necessary. The American diet has a fairly high protein content.

Wang, Hawks, Huddleston, Wood and Smith[14] and others found no relationship between the protein intake and the blood pressure.

Harvey and Howes[15] and others found that wounds heal more quickly under a high protein diet. This is of importance in eye surgery.

CARBOHYDRATES

Carbohydrates, much consumed, produce energy. McCance and Lawrence[16] have contributed data on the available carbohydrate content of different foods.

Carbohydrates[17] may be divided into two groups: 1. The monosaccharides, as dextrose (*d*-glucose), fructose and galactose, all form glycogen and can be absorbed directly into the blood. 2. Polysaccharides are colloids and include starch, hemicellulose, sucrose or sugar, pentosans and celluloses. They occur in grains, vegetable and some fruits. The pentosans and celluloses, little absorbed, are necessary for roughage and stimulating intestinal peristalsis.

Storage of Carbohydrate.—Carbohydrate is stored in the liver, muscles, bones and the skin. Curtailing of carbohydrate in skin diseases, especially eczema of the lids and blepharitis, is necessary.

The Consumption of Carbohydrates.—This has increased enormously. In 1924 the yearly consumption of sugar per capita was 110 pounds, or 547 calories a day. In 1926 a government survey of 80 per cent of the candy makers showed that they produced 1,083,399,754 pounds of candy.

Sugar does not contain a single vitamin or essential mineral salt. Continued consumption of large amounts of nonprotective substances, such as sugar, without a corresponding increase of protective substances may in time react on the body and on a delicate organ such as the eye.

Carbohydrate Requirements.—Voit estimated 500 Gm. a day. For the sedentary person this is too high; from a fourth to a third less is sufficient. Unless hard manual labor is done, the carbohydrate content does not need to be high.

FATS

Fats[17] represent the most concentrated form of energy foods; they are composed of radicals of fatty acids.

Storage of Fat.—Fats are stored in the body, and 0.2 per cent is found in the blood. The synthesis of fat from carbohydrate occurs and a small amount can be formed from protein. Many of the fatty acids combine with phosphorus and nitrogen, forming lipoids.

Sources of Fat.—Fats are obtained from animal and plant life. Fats and oils of the salmon, codfish and other salt water fish have a high iodine content. Eggs contain phospolipin. Butter and cream are important fats, since they contain the fat soluble vitamin A. The substituting of vegetable oils for butter is to be discouraged, since they contain little vitamin A and none of the other vitamins.

Fat Requirements.—About 1 Gm. of fat per kilogram of weight is needed.

MINERAL ELEMENTS

The mineral elements vary in amounts in different foods and also according to the locality from which the food originally came. The function of each mineral element is not yet known and much remains to be found out about their action. Many of them are potent substances playing a unique part in regulating physiologic processes.

VITAMINS

For years it has been known that a diet can be adequate in protein, carbohydrate, fat and inorganic salts but lacking in those substances known as vitamins, and that animals fed on such diets will die. If a small amount of fat soluble A and the water soluble B complex is added to the diet of such depleted animals, a remarkable change will be noted in two or three days. Little is known about the manner in which the vitamins act or about their actual chemical composition. Vitamins appear to be somewhat analogous to hormones.

Six vitamins so far have been demonstrated. These are known as vitamins A (antirachitic, antiophthalmic); B has two fractions, B$_1$ (sometimes called F, antineuritic) and B$_2$ (sometimes called G, antipellagric); C (antiscorbutic); D (antirachitic); E (antisterility). A, D, and E are fat soluble vitamins. The B complex and C are water soluble.

Vitamin A and Infection.—Vitamin A is of special interest to the ophthalmologist. It appears to have considerable to do with preventing infection. The term anti-infective is more appropriate than the earlier terms antirachitic and antiophthalmic. Attention was previously called to the relation of vitamin A to hemeralopia, xerophthalmia and keratomalacia.

Recent researches show that lack of fat soluble A is not the sole etiologic factor in xerophthalmia, but lack of vitamin B, good quality of protein, and possibly an unfavorable salt mixture in the diet also produce an ophthalmia similar to that caused by vitamin A deficiency.[28] However, it is now established that the process of metaplasia of the epithelium and changes in the ducts of the glands is not confined alone to the eye but is general in the respiratory, gastro-intestinal and genito-urinary tracts and is often accompanied by concretions. Cysts and infections of the meibomian glands as well as calcareous deposits in the palpebral conjunctiva are frequent in vitamin A deficiency. Accumulating clinical evidence appears to indicate that some obscure recurrent corneal ulcers, also corneal infiltrations of a dystrophy type, are associated with a vitamin A deficiency.

Pfannenstiel and Scharlau[29] made numerous series of experiments, inoculating rabbits with human pus containing in some experiments staphylococci and in others streptococci, pneumococci or tubercle bacilli. They found that giving vitamin A alone had little effect on staying the infectious process, but when they added B the infections were cut short and healing hastened somewhat on the addition of vitamin D. Vaccines had a more favorable effect when vitamins A and B were used. Mellanby and Green[30] gave vitamin A in puerperal septicemia, mostly of the streptococcus type, reducing the mortality to 28.6 per cent, while in a controlled group receiving no vitamin A the mortality was 92 per cent. This is of use to the ophthalmologist, since violent streptococcus infection of the eye occurs at times, with loss of sight.

The von Eulers[31] and others have isolated from vegetables a substance called carotene, which appears identical with vitamin A in its physiologic effects. This substance is found in carrots, in yellow corn and in the leaves of some plants. Its chemical reaction is not quite identical with vitamin A derived from animals, making it probable that vitamin A will eventually be shown to consist of two fractions, one found in animals and the other in plants.

Storage of Vitamin A in the Body.—Is vitamin A stored in the body, and where? Holm[2] has shown that the retina is rich in vitamin A, since less than 0.75 Gm. daily of retina is sufficient to induce optimal conditions and growth in xerophthalmic rats.

Recently Wolff[22] made studies on the storage of vitamin A. He examined the livers of 600 human corpses and found great variation in the amount of vitamin A stored in those who died of chronic illnesses and those who died of acute illnesses. In thirty-nine patients dying by accident, the average amount of vitamin A was 21.5 units per gram of liver. In 112 dying of acute illness the average was 20.7 units per gram of liver, and in 30.3 per cent of the remainder dying of chronic illnesses the amount was found to be less than 6 units per gram of liver. In many newborn infants the liver did not contain any vitamin A. This last fact is very important, since the greater number of cases of keratomalacia occur in children under 1 year of age. It indicates that the mother should be given a generous supply of vitamin A as well as other vitamins during the prenatal and lactation periods.

Sources of Vitamin A.—Vitamin A is derived from milk, butter, cream, cheese, cod liver oil, egg yolk, fish liver oils, liver, kidney, and roe in animal life, and from carrots, cabbage, collards, lettuce, spinach, tomato, bananas and turnip greens in vegetable life.

Destruction of Vitamin A.—Prolonged contact in open air or long heating in open vessels destroys vitamin A.

Vitamin B.—Recently two independent fractions have been demonstrated in vitamin B. Foods need to be reanalyzed to separate the two fractions. B_1 fraction contains the antineuritic property, and B_2 the antipellagric.

Storage of Vitamin B.—The body does not store vitamin B to any extent; hence the need of sufficient quantities of the B complex at all times. Vitamin B helps maintain the appetite, aids growth, reproduction, lactation, proper function of the digestive tract, including peristalsis, and increases the resistance to infection.

Absence of vitamin B_1 reduces catalysis and results in toxic products effecting the nervous system. Patients with lack of B_1 are nervous and irritable and complain of their eyes tiring easily. Patients with uveitis of obscure origin are often low in the B complex and improve when a rich source of this vitamin is given. B_2 is more resistant to heat than B_1. Absence of B_2 causes signs of ophthalmia.

Sources of Vitamin B.—Little has been done in reanalyzing the B complex foods into B_1 and B_2 (F and G). Few foods appear to contain equal amounts of each. Cereals contain more of B_1 and little of B_2. White flour has relatively little B complex, as the germ part, which is rich in B, is largely lost in milling. Milk and green leafy vegetables are rich in B_2. Bananas have considerable B_2. Yeast contains B_2 and also a fair amount of B_1. Nearly all fruits have some vitamin B; also the vegetables. Liver, kidney, oysters, heart and eggs are good sources of the B complex, probably of the B_2 fraction. Wheat germ is exceptionally rich in B complex. Highly refined foods are poor in B complex.

Destruction of Vitamin B.—Vitamin B is destroyed by the addition of soda in the cooking. B_1 is destroyed by heat.

Vitamin C.—This vitamin is the most unstable of all the vitamins to heat, especially if heated in the open air. Preserved foods, as a rule, except canned tomatoes, cannot be depended on for vitamin C. Absence of scurvy cannot be taken as a proof that there is not a lack of vitamin C. Irritability and pains of a rheumatic nature are many times due to deficiency in vitamin C. Small hemorrhages in the skin, organs, mucous membranes and the bone marrow are characteristic of deficiency in vitamin C. Repeated vitreous and retinal hemorrhages of unknown etiology may be associated with lack of vitamin C and calcium deficiency. Lack of resistance to infection has been noted many times in vitamin C deficiency. Research is making it plain that larger amounts of vitamin C are needed for vigorous health.

Storage of Vitamin C.—The body does not appear to store this vitamin. Scurvy will develop in four weeks in a man entirely deprived of it.

Sources of Vitamin C.—Oranges, lemons, grapefruit, pineapple, raspberries, strawberries and tomatoes among the fruits are high in the amount of vitamin C. Cabbage, lettuce, onions, fresh peas, rutabagas and spinach contain large amounts. Cereals and meats contain practically none. Milk contains only a small amount.

Destruction of Vitamin C.—Alkalis, including soda, destroy this vitamin. Aging and drying lessen the amount of vitamin C. Kohman and Eddy found that if materials prepared for canning were immersed in slightly salted water for a few hours they could be canned without losing vitamin C and the antiscorbutic properties. Unfortunately, few manufacturers of canned goods avail themselves of this research.

Vitamin D.—Vitamin D is ergosterol and its value can be increased by irradiation. So far, D is the only vitamin manufactured from a chemical compound. It aids in the metabolism of calcium and phosphorus.

Storage of Vitamin D.—This vitamin is stored to a slight extent in the body.

Sources of Vitamin D.—Few foods contain vitamin D. Cod liver oil, liver and the yolk of eggs contain large amounts. Milk has a little, and green vegetables small amounts.

Vitamin E.—Vitamin E is necessary for fertility and, according to McCollum, appears to be necessary for assimilation of iron. Vitamin E is resistant to heat.

Sources of Vitamin E.—This vitamin is found in vegetable oils. Wheat embryo furnishes a very potent form of it. Small amounts are present in meats, milk and cream.

Destruction of Vitamin E.—Evans and Burr [32] have clearly demonstrated that lard and rancid fats are capable of destroying vitamin E.

NEUTRALITY OF BODY AND FOOD INTAKE

It appears that the subject is very complex. At least six of the mineral salts enumerated, several constituents of the protein group, a small amount of fat, a considerable amount of dextrose of the carbohydrate group, and small amounts of other important body constituents are found in the vitreous and aqueous of the eye.

It is evident that even a slight variation between the salts and constituents of the blood plasma and the tissues of the uvea—with its enormous capillary system, the latter acts as an osmotic system—and the colloidal vitreous on the other side will at once react on the metabolism and nutrition of the eye. It seems most probable that cataract and glaucoma are due to physicochemical upsets in the equilibrium between this osmotic system of the uvea and the vitreous and aqueous; the whole process is but a manifestation of a similar condition in other parts of the body and the primary cause arises from improper intake of essential elements and substances in the diet, which in time lessen the resistance to infection, give rise to intestinal toxins, place added burdens of elimination of excess salts and deleterious substances on the kidney, and induce changes in the permeability of the walls of the blood vessels.

The body must be furnished with an adequate supply of foods containing sufficient essential mineral salts, vitamins and proper proportions of acid and base forming substances to maintain the body neutrality and a good state of nutrition. How can this be done? I answer, by choosing a diet of milk and its products, eggs, green leafy vegetables, fruits and a small amount of meat and by restricting the intake of cereal grains and other carbohydrates.

Amount of Food.—What about calories, standardization of diets, highly concentrated foods and the many widely advertised foods? How much food or how many calories depend on the occupation, the activity of the individual, the age, the weight, and the condition of the health. Diet is largely an individual problem. The undue attention given to the calories and excessive standardization are to be deplored. The biologic values of the foods used and the individual requirements are of far more importance. Most of the foods extolled in the advertising literature as having exceptional nutritive qualities do not measure up to the claims made. They are expensive and too often represent the propaganda of vested interests.

Food must be assimilable and palatable. Much roughage is not advisable. For the average sedentary worker the allowance of carbohydrate should be comparatively small. The total calories need to be about 2,000 to 2,500 daily. For the one engaged in considerable muscular activity the carbohydrate intake must be larger and the total calories need to be increased to 3,500 and in some cases more. Usually proteins do not need to be increased, but the quality must be considered.

There is a growing indication that the amount of vitamin C is too low. To increase it, oranges and the juice of a lemon besides one or two of the vegetable foods such as lettuce, cabbage, spinach and tomato should be taken.

More vitamin A is needed in most dietaries; additional milk, cream and butter, bananas, carrots, lettuce, spinach, liver and eggs should be used.

Vitamin B, on account of its usefulness in stimulating the appetite and combating constipation and because of its antineuritic and antipellagric properties, should be employed in the diet in the form of beans, peas, carrots, cauliflower, celery, liver, beef, egg yolk, lemons, milk, peaches, pineapple, potato, spinach, tomato, turnips, graham bread, yeast extract and wheat germ.

People must get away from the regulation cereal, bread, meat, potato and rich pastry diet. Diets containing too much carbohydrate ferment easily in the intestine, producing irritating substances. Highly seasoned foods are to be avoided. Too high a fat diet, lacking in sufficient mineral salts, vitamins and a proper amount of carbohydrate, is unadvisable. In addition to beef, lamb and other meats, the diet should include liver, kidney, pancreas and brains.

Preparation of Food.—The preparation of foods should conserve the vitamins and mineral salts. Vegetables should not be immersed in large quantities of water when cooked but should be either steam-cooked or cooked in such a manner that the salts will be left in the vegetables and not dissolved out. Salt should be used sparingly. Vegetables should not be cooked too long. It is well to use some raw, finely divided foods, such as cabbage, celery, carrots, lettuce and fruits, daily.

Allergy.—Can foods ever cause anaphylactic reactions in the eye? My answer is yes. About 45 per cent of allergic patients exhibit sensitiveness to wheat preparations; about 20 per cent to eggs, vegetables and fruits; and about 10 per cent to fish, chocolate and other foods. Conlon [33] describes allergy in the eye due to foods and the reader is referred to the works of Duke, Vaughn and others for a fuller description of allergy.

CONCLUSIONS

Evidence is set forth showing that one of the most constant signs of food deficiency is the pigmentation of the conjunctiva and the reduction of the light sense. The retina stores vitamin A, and an avitaminosis causes an increase of lipoids in the rods of the retina and decreases the visual purple. Lack of vitamin A has been responsible for epidemics of hemeralopia, xerophthalmia and keratomalacia. Vitamin A is largely stored in the liver and is much depleted in chronic illnesses; it appears to be concerned largely with preventing infection.

Vitamin B is necessary to good nutrition. Lack of B_1 causes nervousness and irritability, and patients complain of the eyes tiring easily. Vitamin B concentrate added to the diet of those suffering from uveitis of unknown etiology is beneficial.

A lack of vitamin C, combined with a calcium deficiency, may be responsible for repeated vitreous hemorrhages of unknown etiology.

The mineral salts are potent substances concerned in regulating the physiologic processes of the body. Calcium is more frequently deficient in American diets than any of the other mineral elements. Calcium deficiency occurs in vernal conjunctivitis.

The complexity of the protein constituents of foods is shown. Proteins of poor quality can cause ophthalmia.

[33] Conlon, F. A.: Am. J. Ophth. 2: 486, 1919.

The consumption of carbohydrates is often two or three times the amount required for good nutrition. Excessive use of carbohydrates has been known to cause inflammatory diseases of the eye.

Excessive fat diets deficient in mineral elements and vitamins cause hyperplasia of the tissues.

The problem of food intake concerns itself with sufficient mineral elements and protective substances to maintain proper equilibrium of the body fluids and tissues.

Note.—Tables showing the various mineral constituents of foods; also the protein, carbohydrate and fat content of the edible portions and the vitamins were shown in lantern slides and will appear *in the transactions of the section*, as well as in the author's reprints.

ABSTRACT OF DISCUSSION

Dr. Albert N. Lemoine, Kansas City, Mo.: It is generally agreed that the thyroid secretion acts as a catalytic substance expediting chemical changes in the cells of the body, while the parathyroids control the calcium exchange in the body. With a deficiency of parathyroid with a normal calcium intake, one finds calcium in the stools, and a decrease in the calcium in the tissues; consequently a high calcium diet is of no avail if one has a parathyroid dysfunctioning. The anterior lobe of the pituitary controls growth and metamorphosis, while the posterior lobe assists in the control of the carbohydrate metabolism and the urinary output. The suprarenals stimulate the smooth muscles and act as a control of anaphylactic reactions. The discoloration of the skin in suprarenal deficiency greatly resembles that noted in some of the deficiency diseases. The pancreas secretes multiple ferments that control intestinal digestion of foods, especially the fats, and its internal secretions control the metabolism of dextrose. With these facts in mind, one can readily see that it is not possible to outline a diet that will meet the requirements of all patients from the mineral, the caloric or the vitamin standpoint. But one must understand the needs and deficiencies of each individual patient to prescribe the proper diet intelligently. However, it is quite true that a diet containing the proper proportions of minerals, carbohydrates, fats and pretein with a good proportion of all the vitamins will certainly act favorably in most eye diseases. I agree with the author that most patients with vernal catarrh have a low blood calcium, as that has been my experience with these patients, but in some severe cases I have had a normal blood calcium. I do not believe that the low blood calcium is due to a deficient calcium intake; it probably is due to a hypoparathyroidism causing a faulty calcium exchange. It has been my experience that in most cases an increase of calcium intake did not increase the blood calcium, but, given with parathyroid, in most cases calcium did increase the calcium content of the blood.

Dr. I. S. Tassman, Philadelphia: I have maintained young rats on a diet deficient in vitamin A until the early ocular signs were noted, which cleared up by the addition of cod liver oil to the diet. This was in accord with the results obtained by others. More recently, vitamin A has been credited with growth promoting rather than ophthalmic properties and its absence from the diet of animals has been shown to produce lesions in many other organs with death of the animals before any marked ocular lesions developed. Green and Mellanby even found that vitamin A had an anti-infective property and claimed that at least it had a pronounced action in raising the resistance of the patient. As was noted in the paper, this should be of importance in the treatment of certain ocular conditions. From a practical standpoint, it is no doubt true that in many patients with ocular conditions there exists a deficiency or at least a partial deficiency of some of the essential food factors, particularly vitamin A. Pillat, who has studied many of these cases in northern China, has classified the ocular symptoms and signs resulting from vitamin A deficiency in a detailed form. Night blindness, loss of luster of the conjunctiva with bulbar injection, slight discharge and pigmentation of the conjunctiva, blepharitis, and hordeolum might all occur as early signs. Any one of a number of well known reasons may exist to cause an individual to maintain a uniform diet over a long period of time. Moreover, such a diet is apt to be deficient in the essentials. In the management of such cases as chronic blepharitis with crust formations on the lid margins, the ordinary subacute and chronic forms of conjunctivitis, recurrent hordeolum and chalazion, phlyctenular conjunctivitis and keratoconjunctivitis in children, episcleritis and simple ulcers of the cornea, a detailed inquiry into the diet of the patient to obtain exact knowledge of the foods included and those omitted will often reveal a real deficiency, which if corrected will do more to correct the ocular disturbances than the local treatment ordinarily used.

Dr. Laura A. Lane, Minneapolis: I feel that the iodine which one gives to patients in their food will activate a deficient thyroid, and Dr. Clark's work at the University of California seems to show conclusively that the green leafy vegetables help to fix the calcium. I hope that these patients will be treated as individuals, not in a wholesale fashion. It is an individual problem.

PNEUMOCOCCUS PSEUDOMEMBRANOUS PHARYNGITIS

REPORT OF FIVE CASES TREATED WITH ETHYLHYDROCUPREINE HYDROCHLORIDE *

deWAYNE G. RICHEY, M.D.
PITTSBURGH

In choosing to touch on such a shopworn theme as the microbic aspect of disease, one is enjoined by propriety to select for discussion significant facts regarding fundamental phases of the subject. Accordingly, this communication will endeavor: (1) to set forth the outstanding clinical features as observed in five persons suffering from acute pseudomembranous pharyngitis; (2) to emphasize that the pneumococcus as the apparent causal agent was revealed by appropriate bacteriologic examinations on carefully selected material, after repeated previous similar examinations on "routinely" taken swabs had failed to indicate this etiologic relationship; (3) to call attention to the therapeutic efficacy of ethylhydrocupreine hydrochloride, which was suggested by the bacteriologic observations, after all attempts to alter the course of the condition by innumerable local and general remedial agents proved futile; and, finally, to impress the fact that only by close cooperation between the clinician and the laboratory worker can even the simpler laboratory methods be made useful.

SUMMARY OF CLINICAL DATA

As there was no variation in many of the clinical manifestations throughout the entire group, the data will be considered collectively.

All of the five patients included in the series were adults; three were women, aged 20, 36 and 43, respectively; the two men were 24 and 80.

Save one, all were in good physical condition. The exception was a clergyman, aged 80, who had an advanced arteriosclerosis.

There was no suggestion of a determining epidemiologic factor, such as climate, season, social status, contact infection, or associated injury or illness. All cases were sporadic.

As indicated in the table, the onset of the attacks was usually rapid, being attended by a fever of from 100 to

---

* Read before the Section on Laryngology, Otology and Rhinology at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 10, 1931.

102 F. and malaise. In case 4 the onset was sudden, with fever as high as 103 F., chills, myalgia and headache. The elderly man (case 5) showed few if any systemic constitutional manifestations. In fact, the systemic reaction to the infection showed greater variation than any other clinical feature. However, recurrent attacks were constant in the given person.

A remarkable constancy obtained in the local symptoms, which invariably were a severe sore throat, dysphagia and tender regional lymph nodes. The pain was described as being throbbing, burning or scalding. It was associated with a feeling of stiffness of the throat. These two symptoms led to a dysphagia that precluded ingestion of food and sometimes of liquids, for a week or more.

DESCRIPTION OF THE LESION

Site of Origin.—As shown in the table, in three cases the infection began in the pharynx and in two, on the floor of the mouth. Tonsillar tissue afforded the place of beginning in two of the three cases. However, in one instance a successful tonsillectomy did not prevent a recurrence (case 2) or an initial attack (case 4).

Analysis of Five Cases of Pneumococcus Pseudomembranous Pharyngitis Treated with Ethylhydrocupreine Hydrochloride *

Case	Sex	Age	Number of Former Attacks	Duration of Former Attacks, Days	Site of Orig n of Pseudomembrane, All Attacks	Anatomic Distribution of Pseudomembrane, All Attacks	Present Attack; Character of Onset	Number of Days Before Treatment with Ethylhydrocupreine	Number of Days of Treatment	Comment
1	♀	43	6	14-21	Left tonsil	Entire oropharynx	++	3	5	Pharynx cocainized before adm'nistration of ethylhydrocupreine; tonsillectomy and adenoidectomy one month later
2	♀	20	2	10-14	Nasopharynx	Postpharyngeal wall	++	2	4	Tonsillectomy and adenoidectomy one year ago after two similar attacks
3	♂	24	3	10-14	Right tonsil stump	Entire oropharynx	++	2	4	Incomplete tonsillectomy and adenoidectomy three years ago for similar condit.on; secondary tonsillectomy and adenoidectomy three months later
4	♀	36	. .	...	Floor of mouth	Entire cavum oris	+++	4	7	Associated gingivitis (Vincent's) requiring solution of potass.um arsenite; pat'ent died two years later of pneumonia; previous tonsillectomy and adenoidectomy
5	♂	80	?	....	Floor of mouth	Entire cavum oris	+	10	7	Patient was moribund at time and died of advanced arteriosclerosis two days after disappearance of pseudomembrane

* In th's table, ♂ denotes male; ♀, female; +, an insidious onset with no systemic reaction; ++, a rapid onset with moderately pronounced constitutional symptoms; +++, sudden onset with marked constitutional reaction.

Extent of Involvement.—Both cases originating on the floor of the mouth extended along the plica sublingualis to involve the pharynx. The lesions beginning in the pharynx did not spread anteriorly. In no instance was the tongue or the vestibule involved. Macroscopically, the exudate was very similar in appearance in all cases. The mature pseudomembrane was white, shiny, smooth and odorless. It was thick and surrounded by a narrow red areola. Being leathery, it was "diphtheritic." However, this term has been avoided purposely so as to obviate etiologic confusion. The membrane was fairly adherent, especially at the advancing border. As it separated, an extremely superficial base, composed of an eroded, frosted mucous membrane, stippled with petechiae, was seen. There was no destruction of tissue, and healing occurred rapidly, without scarring. It was perhaps less leathery, more friable, less adherent than the true *diphtheritic* pseudomembrane. However, this distinction was by no means sufficiently definite to be of convincing diagnostic value. Microscopically, the membrane was found to be a homogeneous mass of fibrinous coagulum almost devoid of cellular elements. It is important to note that the bacteria were never numerous and occurred in the deeper zone, especially at the advancing margin.

Laboratory Observations.—The leukocyte counts ranged from 6,600 to 9,500. Differential counts in two cases showed the normal ratio of the leukocytes.

Save for a trace of albumin in two cases, urinalysis gave negative results.

The complement fixation test for syphilis was negative in each case.

Bacteriologic Examination.—Unquestionably, the recognition of the pneumococcus as the predominant bacterium in each member of this series ultimately depended on appropriate bacteriologic examination of intelligently selected material. The previous failures of similar bacteriologic methods to place this microorganism in the light of at least a possible causal rôle on materials from the same persons neither condemns the method nor incriminates the examiner. It does, however, emphasize the necessity for a close cooperation between the clinician and the bacteriologist and, consequently, places a responsibility on the practitioner to see that representative material is procured for examination.

Only by obtaining a piece of the fibrinous exudate from the advancing border can one expect to gain accurate information as to the bacterial flora of the lesions. Without exception, loose or entirely separated pieces of membrane yielded a host of habitués among the oral flora, which had long since overgrown the pneumococcus.

The methods employed in this investigation represent a standard procedure with us and involve ordinary forms of bacteriologic technic; namely, (1) direct smears of crushed exudate stained by Gram's method, by Loeffler's alkaline methylene blue (methylthionine chloride U. S. P.) and by dilute carbolfuchsin (1 : 10); and (2) cultures on Loeffler's serum medium and on plain serum broth, with subsequent isolation and identification of the various parasitic types.

The pneumococcus is a lanceolate, gram-positiv encapsulated diplococcus, forming a round umbilica greenish colony on blood agar; it is bile soluble and usually ferments inulin.

Briefly, then, the pneumococcus was recognized as the predominating organism in each of the five cases, when newly formed exudate was examined. It occurred in pure culture on two occasions, and in symbiosis with a few well known members of the oral flora in the other three instances. Of the isolated strains of pneumococcus, three were subjected to serologic tests, and all fell in the large miscellaneous group commonly called type IV. No virulence determinations were made.

Among those instances that yielded other organisms in addition to pneumococci, one deserves comment. A large number of the fusospirillary forms commonly associated with Vincent's angina occurred, with a hemolytic streptococcus (Streptococcus pyogenes). Clinically, there was an extensive gingivitis along the alveolar ridge of the lower jaw (case 4).

TREATMENT

It was the recognition of the pneumococcus in practically pure culture in the first case that suggested the use of ethylhydrocupreine (optochin) hydrochloride, an alkaloid related to quinine and of high pneumococcidal properties. To the lesions of the first patient, an introspective woman, was applied by cotton applicators a fresh aqueous solution (1 per cent) of ethylhydrocupreine hydrochloride. So painful was the procedure that the treatment was repeated only once a day after preliminary cocainization. In the remaining cases a 2 per cent solution was used, sometimes as often as every two hours, following partial disintegration of the pseudomembrane by fresh hydrogen peroxide. None of these patients complained of pain.

Reference to the table will give some idea that the gratifying therapeutic response was not only in shortening the course of the infection but more particularly in the almost immediate alleviation of pain, salivation and dysphagia. In the two cases that required a week for the exudate to disappear, one had a marked gingivitis which required the administration of solution of potassium arsenite (Fowler's solution) and later the extraction of the lower teeth. In the other patient, a moribund old man, the exudate disappeared entirely in a week, and two days later he died in his sleep. No toxic manifestations appeared in any patient.

LITERATURE

The relevant literature has been surveyed with reasonable diligence. No attempt has been made to expiscate articles consigned to oblivion. The number of references found was relatively few. In most of the older cases, convincing evidence as to their true pneumococcic pseudomembranous nature is lacking. Most of the reports appear in the French literature: Reh[1] reports nine cases; Riser and Bert,[2] two cases (all in children). Reich and Schomerus,[3] in Germany, mention ten instances involving the pharynx. Heindl,[4] in describing a personal case, mentions two reported by Paltauf and six by Koritschoner. A good instance appears in a report by Ramos.[5] Many of these cases present bacteriologic and clinical conditions similar to my cases.

A good many instances of a pneumococcic pseudomembranous lesion in the nose and trachea have been reported. More, however, appear to have been due to streptococci. Of course, the vast majority are caused by Bacillus diphtheriae. Deep, ulcerative lesions were noted by Semon[6] and by Foster.[7]

Since Morgenroth and his co-workers[8] in 1911 isolated ethylhydrocupreine, it has been used in the treatment of various types of pneumococcic infections, notably in conjunctivitis, empyema, meningitis and lobar pneumonia. The best results have been seen in cases presenting conjunctivitis and empyema.

In most of the cases in the literature any efforts at specific therapy have been confined to vaccines and serums. I have been unable to find a formal account of the treatment of acute pneumococcic pseudomembranous pharyngitis by ethylhydrocupreine.

SUMMARY AND CONCLUSIONS

1. Pertinent bacteriologic and clinical data from five adult persons suffering from an acute pseudomembranous pharyngitis, beginning in two cases as a stomatitis, are presented.

2. In all the cases a typical pneumococcus was found, by standard bacteriologic methods of examination of the fibrinous exudate, to be the dominant micro-organism.

3. Clinically the local symptoms are constant and consist of a severe sore throat, salivation, dysphagia and cervical adenitis; the systemic reaction varies considerably.

4. The characteristic lesion is uniformly found: a white, fairly tough, fairly adherent, odorless sheet of fibrin on a superficially eroded oropharyngeal mucosa. It is very similar to the *diphtheritic* pseudomembrane caused by the Klebs-Loeffler bacillus. Diagnosis should be made by bacteriologic examination.

5. The condition does not endanger life as a rule; attacks tend to recur.

6. The lesion resists most types of local and general therapy.

7. Striking results were obtained by the topical application of ethylhydrocupreine hydrochloride.

8. The cardinal importance of a close cooperation between the clinician and the bacteriologist is stressed.

ABSTRACT OF DISCUSSION

Dr. Walter Roberts, Philadelphia: In going over a copy of Dr. Richey's paper, which he sent me a few days ago, I was impressed with the fact that it contained much that was new to me. I am willing to admit that I had not realized the important part that the pneumococcus sometimes plays in throat infections. Those of us who have had many years' experience in the treatment of pseudomembranous pharyngitis and have felt that we were fairly competent in the diagnosis and treatment of the various conditions which we encountered may now feel a little chagrined that we failed to recognize this pneumococcic type of the disease. The diphtheritic, the streptococcic and the Vincent's angina membranes all have their appropriate treatments and usually are satisfactorily dealt with, but occasionally we have not achieved the rapid results that we expected, and now in looking back I should not be surprised if the pneumococcus was to blame. It is very possible that they were mixed infections and our treatments had no effect on the pneumococcic side of the trouble. In these days when our colleagues in the laboratory are ever ready to help in our diagnosis and treatment there is no excuse for our failing to recognize these pneumococcic, pseudomembranous pharyngitis cases and

to give them the appropriate care. We must not forget that a diagnosis of the condition under discussion can be made only by a careful bacteriologic study. In the future, when I meet a pseudomembranous pharyngitis that does not respond to the usual treatments, I shall see to it that a careful bacteriologic study is made, and if there is a predominance of pneumococci, I shall apply 1 per cent solution of ethylhydrocupreine.

Dr. Horace James Williams, Philadelphia: Little has been written in either the English or the American literature concerning pneumococcus pseudomembranous pharyngitis. In 1908, Henry Albert of Iowa City reported his observations of pseudomembranous inflammations of the pharynx caused by staphylococcus, streptococcus, Vincent's organism, and Micrococcus catarrhalis. In his observation the streptococcus was most often the offending organism. Vedal reported a similar epidemic of pneumococcic angina in which five cases occurred, with three deaths. In 1909, John Elliot reported in the *British Medical Journal* an epidemic of pneumococcic pharyngitis occurring at the same time as an epidemic of pneumonia. Most of his cases showed the pneumococcus present in the pharynx but without a membrane. Sir Felix Simon described several cases of ulcerative pharyngitis with perforation of the palate and brought considerable evidence to show that they were pneumococcic in origin. I have seen but one case, and this might be questioned. In a boy, aged 10 years, an acute pharyngitis developed, with a temperature ranging from 100 to 101 F., and a marked angina. The pharynx was covered with a yellowish exudate, and at first the condition was thought to be diphtheria. The culture revealed the presence of pneumococci. The patient was treated with 1 per cent solution of ethylhydrocupreine after the membrane had been removed. By the eighth day the membrane had disappeared and the patient's symptoms rapidly subsided.

Dr. de Wayne G. Richey, Pittsburgh: While I cannot bring myself to accept in full measure their generous remarks, Drs. Roberts and Williams have encouraged me to continue that which was previously foreshortened by time. The poikilonymous title "Pneumococcus Pseudomembranous Pharyngitis" was designed to connote the chief sources of its subject's data, bacteriologic, pathologic and clinical; to imply a probable pneumococcic origin for these five cases, an inference consistent with the evidence, but not necessarily to pose the pneumococcus as the specific etiologic agent—an assumption neither justified by the facts nor essential to the propositions of this discussion. Moreover, "pseudomembranous pharyngitis" is not recognized as a pathologic process or a clinical entity peculiar to pneumococci. Indeed, "pseudomembranous" is employed purely in an anatomic sense to indicate a membrane-like expanse of solidified fibrinous exudate, with or without subjacent necrosis. It embraces, therefore, terms like "croupous" and "diphtheritic," and symbolizes the defensive and protective response of oropharyngeal mucosae to irritants of degree rather than of kind, particularly bacteria and notably Corynebacterium diphtheriae, Streptococcus hemolyticus and Pneumococcus. Conceding the supremacy of the Klebs-Loeffler bacillus, one wonders why pneumococci—arch elaborators of fibrin on superficially denuded mucosal epitheliums—have been encountered less frequently than the common pyogenic hemolytic streptococci. One wonders, too, that most of the recorded attempts at specific treatment have been confined to serum therapy, because, by virtue of acuteness, superficiality, ready regional accessibility and low absorbability, this condition meets virtually all the essential requirements for successfull chemotherapy. Even so, and admitting ethylhydrocupreine's high pneumococcidal properties in vitro, one encounters two formidable barriers to local chemotherapeutic idealism: the relatively slow action of ethylhydrocupreine in vivo and the low penetrability of aqueous solutions. In practice, these hazards can be circumvented best by frequent topical applications (as often as every hour, if necessary) and by disintegration of the false membrane by fresh hydrogen dioxide. Under no circumstances should the pseudomembrane be removed forcibly, since it provides a scaffolding conducive to scarless healing. But, above all, it must be remembered that rational specific therapy depends on correct bacteriologic diagnosis, which in turn depends on well devised examinations on astutely chosen materials.

Clinical Notes, Suggestions and New Instruments

HENDERSON IMPROVED STAIN FOR STIPPLE CELLS

W. E. Deuel, M.D., Pennsgrove, N. J.

To those interested in blood work in connection with the lead industry, I wish to suggest the use of a stain for stipple cells that has proved superior to all others that have been used in an industrial hospital with which I am associated.

This stain was developed by Carl W. Henderson, laboratory technician, du Pont Dye Works Hospital. He examines an average of ninety smears a week and with the usual method of staining too much time was required. With the Henderson method only about one-half minute is required, as compared to five minutes with other stains.

There is no precipitate, making it easier, therefore, to distinguish the basophilic granular cells. The contrast is greater and there is only one step in staining the smear.

Methylene blue	3.75 Gm.
Gentian violet	1.00 Gm.
Add:	
Sodium hydroxide, 10 per cent	5 minims
Methyl alcohol, q. s. ad	250 cc.

Blood smears do not need to be fixed. A Coplin jar is used. Smears are placed in the Coplin staining jar of solution for about one minute, washed with dilute ammonia water, and then rinsed with distilled water. Acetone free alcohol is used.

Dilute ammonia solution:	
Stronger ammonia	5 cc.
Distilled water	3,000 cc.

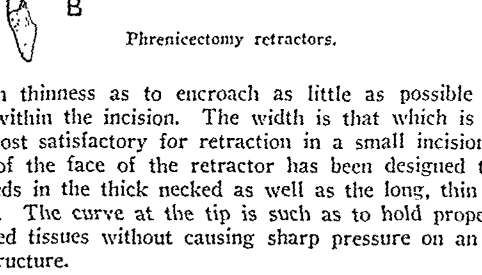
34 Ziegler Tract.

NEW PHRENICECTOMY RETRACTORS

W. E. Delaney, Jr., M.D., Williamsport, Pa.

Proper retraction in phrenicectomies is the most important factor in the skilful and speedy completion of the operation through an incision of minimum length. Retractors in present use have been found unsatisfactory because of their width, thickness, narrowness, shortness or other disproportion.

In order to secure retractors to meet all needs in the operation, I have designed the instruments[1] illustrated here and have found them entirely satisfactory. The instruments are made of such thinness as to encroach as little as possible on the space within the incision. The width is that which is considered most satisfactory for retraction in a small incision. The depth of the face of the retractor has been designed to meet the needs in the thick necked as well as the long, thin necked patient. The curve at the tip is such as to hold properly the retracted tissues without causing sharp pressure on an important structure.



Phrenicectomy retractors.

In order to remove the assistant's hands from the operative field and to make it comfortable for the assistant as he reaches across the patient, the handles of the retractors have been constructed with differing curves for lateral and medial retraction. Retractor *A*, with the concave handle when the instrument is in position, is for retraction laterally on whichever side the incision is made. Retractor *B*, with the convex handle, is for medial retraction. The two retractors are used simultaneously, and the pull of each is enough to offset the pull of the other. The use of these retractors permits exposure of the phrenic nerve through the smallest possible incision and should be helpful to surgeons performing this operation.

Council on Physical Therapy

The Council on Physical Therapy of the American Medical Association has authorized publication of the following article.
H. A. Carter, Secretary.

COLON IRRIGATIONS

THEIR ADMINISTRATION, THERAPEUTIC APPLICATION AND DANGERS

WALTER A. BASTEDO, M.D., Sc.D.
NEW YORK

The colon irrigation has come into extensive use for the removal from the bowel of abnormal mucus, toxic products and bacteria; therefore, as part of our therapeutic armamentarium, it deserves consideration. Between enemas and irrigations there would seem to be no sharp dividing line, yet they are distinct in their purposes. In medicine, the term irrigation conveys the idea of washing; therefore, while the ordinary enema is given with the purpose of inducing defecation, the irrigation is administered, not to induce defecation, but to wash out material situated above the defecation area and to lavage the wall of the bowel as high as the water can be made to reach. To accomplish its purpose an irrigation requires (1) that the fecal mass in the lower colon shall have been expelled and (2) that the liquid shall be passed into the colon so gently that it does not arouse the defecation reflexes. Otherwise it is not a properly given irrigation.

METHODS OF IRRIGATION

There are two primary methods in common use, the one tube and the two tube. With either method the intelligence, skill and experience of the nurse count for much in obtaining results.

The One Tube Method.—This involves filling the colon to capacity through a single tube and then allowing the liquid to run out through the same tube, the process being repeated a number of times. The tube most favored is velvet-eyed with closed end, number 34 French, and is inserted about 6 inches. As demonstrated by roentgenograms, when the ordinary colon tube is passed beyond 6 or 8 inches, it coils up in the upper rectum and, no matter how much of the tube is inserted, it rarely enters the descending colon. There is therefore no benefit to be derived from passing a long colon tube 18 or 20 inches to form such a coil in the rectal ampulla.

Tubes of large caliber, number 38 to 50 French, are also sold for irrigation purposes. Their advocates claim that after the sigmoid flexure is washed out the end of the tube may be pushed on to the splenic flexure for cleansing the descending colon, then to the midtransverse colon or hepatic flexure for cleansing the transverse colon and then to the cecum for lavage of the cecum and ascending colon. One of these advocates asserts that "a stiff colon tube in the bowel will render it powerless to coil or form loops." He shows several pictures in which the end of the tube is in the transverse colon or hepatic flexure and one in which, *after the insertion of 69 inches of tube*, the end is practically in the cecum.

The passage of such a heavy stiff piece of hose for more than a few inches I consider a dangerous procedure. Moreover, the high insertion is unnecessary, for the universal use of the opaque enema in roentgen work has demonstrated beyond question that with a tube inserted 3 or 4 inches into the rectum and a pressure level of 2 feet, the liquid will reach the cecum in from two to five minutes. There is no specific difference, therefore, between a "low irrigation" and a "high irrigation," and such misleading terms should be abolished. In reporting his roentgen studies with enemas of a mucilaginous suspension of barium followed by irrigation with the large single tube, Fineman remarks: "In a few cases with the tube in the sigmoid and even in the transverse colon or cecum, a great amount of the barium remained in the colon after the irrigation . . . In some cases there was better emptying from a 4 inch tube than from one passed into the cecum . . . As yet final deductions concerning the necessity or advantage of introducing the tube far into the colon are not warranted."

The Two Tube Method.—This employs separate inflow and outflow tubes and is the method that I prefer. It seems to me more successful in promoting relaxation and avoiding over-distention. For the inflow I use a soft rubber velvet-eyed catheter, number 20 to 24 French, inserted from 5 to 6 inches, and for the outflow, a velvet-eyed closed-end rectal tube (or stomach tube), number 30 or 32 French, inserted from 3 to 4 inches. The patient is placed on an ordinary mattress couch, rather than on some elaborately built and patented table. The details of the method are as follows:

DIRECTIONS FOR THE NURSE

1. If the patient has not defecated, empty the bowels with a plain water enema and wait fifteen minutes for the defecation reflexes to quiet down.
2. For the first gallon have the patient lie on the left side with the knees drawn up. After that have the patient lie on the back.
3. Hang the reservoir so that its midlevel is not more than 2 feet above the rectum.
4. Having freely lubricated the tubes with white petrolatum, have the patient bear down as at stool and insert the inlet tube 5 or 6 inches, allowing the water to flow during its insertion. Then insert the outlet tube 3 or 4 inches.
5. Use plain water at or just above body temperature, and let it run in slowly to avoid arousing the defecation reflexes.
6. If the outlet tube becomes plugged, inject a little water through it with a hand bulb. If this does not clear it, withdraw it without disturbing the inlet tube, clean it and reinsert.
7. Terminate the irrigation when convinced that the colon is clean or when you think the treatment has been sufficiently prolonged. We expect an irrigation to consume from 6 to 10 gallons and to take nearly an hour.
8. After the irrigation, have the patient empty the bowels into the toilet. Examine this return before the toilet is flushed.
9. Report particularly on the various odors and on the amount and character of the mucus, feces and recognizable food particles in each gallon of the returns.

THE LIQUID EMPLOYED

Because of the large amount of liquid introduced, I use plain water. Sodium chloride solution has not shown any advantage and, in some cases, makes the patient thirsty and unduly activates the bladder. Sodium bicarbonate solution is frequently employed as a solvent for mucus. But it does not dissolve the thick heavy masses of mucus found in mucous colitis; it unduly activates the kidneys; it may overalkalize the bowel and the patient; and, not infrequently, it generates undue amounts of gas. I have had a number of complaints of colic from sodium bicarbonate, while in the same patients plain water did not arouse colic. With roentgenograms, Fineman showed that plain water is more cleansing than solutions of sodium chloride or sodium bicarbonate. I do not suggest that saline of sodium bicarbonate solutions should never be used, but as a routine I prefer plain water. Sodium carbonate (washing soda) dissolves mucus better than does sodium bicarbonate and generates less gas, but it is a much stronger alkali and it has caustic properties. In my opinion it should not be introduced into the colon.

I do not ordinarily employ astringents or antiseptics. The strongest antiseptics permissible in the bowel do not kill the bacteria and are prone to be injurious to the wall of the colon. The Dragstedts and Nisbet at the Mayo Clinic showed the impossibility of sterilizing the intestine by ordinary antiseptics. In tied off intestinal loops they placed 70 per cent alcohol, ether, a 2 per cent compound solution of cresol, 5 per cent silver nitrate, a saturated solution of zinc chloride, 5 per cent phenol, 10 per cent thymol in alcohol, a saturated solution of phenyl salicylate, a saturated solution of quinine sulphate, surgical solution of chlorinated soda, a solution of mercuric chloride, and the solids, camphor, menthol, naphthalene and betanaphthol. In all these cases they failed to obtain sterilization. How, then, could an antiseptic effect be expected from the weak solutions permissible for irrigation purposes? The bowel is freed from bacteria much more by washing out its contents and by the removal of masses of mucus which cling tightly to the mucous membrane and harbor innumerable bacteria between this and the mucous sheet.

I use from 6 to 10 gallons of fluid at a temperature of about 100 F. Weitz and Vallers find that both heat and cold lower the tonus of the colon but that the heat effect is stronger and more lasting. Possibly a hotter fluid might be of benefit when the colon is irritable.

FURTHER CONSIDERATIONS

Irrigations are not given to move the bowels but rather to reach the regions beyond the defecation area of the left colon, the regions not cleaned out by defecation. Just as a stomach is lavaged with water until it is clean, so is an attempt made to lavage the colon until it is clean. True, one can fill the colon with 2 quarts of water, have it pass to the cecum in two or three minutes, as shown by roentgenograms, and have it reexpelled. But this does not suffice. In mucous colitis the thick tenacious mucus may take a lot of soaking before it can be liberated from the mucous membrane to which it clings so tightly. At autopsy I have found it a difficult matter to remove this mucus even with forceps and under a strong stream of water. Moreover, the site of the putrefaction or infection, as shown by Herter and others, is not infrequently the terminal foot or two of the small intestine. After several gallons had been used in washing the colon, with the patient quite relaxed, and even after an enema had been given, it has been my experience in numerous cases suddenly to obtain rotten putrefying material, as if the ileocolic sphincter had just opened and let down bad ileal contents.

When an irrigation is unsuccessful in obtaining the mucus, a brisk cathartic given the same night may result in the passage of large quantities of mucus, apparently softened by the water of the irrigation, and sometimes in the passage of foul putrefactive stuff, presumably from the small intestine and completely missed by the 6 or 8 gallons of water employed in the irrigation. When the mucus proves regularly to be loosened with difficulty, I give a small dose of phenolphthalein the night before or a small dose of salts the morning of the irrigation. Cleaning diseased bowels is not an easy task, and Alvarez and Freedlander have shown that even in the normal bowel sidetracking is a common trick. They gave normal persons small beads with their food and found that many days and even weeks elapsed before the last beads were passed in the stools. Some of the subjects with apparently normal movements took a week to pass as much as 70 per cent of the beads. One person whose bowels were constipated did not pass the last of the beads until the fortieth day.

It must be evident that if the whole colon is irrigated the water cannot return clear, and that a "clear return," as so frequently reported by the unspecialized nurse, means that the water did not get up. In many of our hospitals only twenty minutes are allowed to prepare for and give an irrigation; it is often given between 7 and 8 o'clock in the morning before the bowels have had a chance to move; there is no effort to obtain a movement of the bowels in advance of the irrigation; and the bag is placed 4 or 5 feet high so that the water can be rushed in. This is not a proper irrigation.

For ordinary mucous colitis, putrefaction or focal infection cases I employ the irrigation two or three times a week at first, then every five days, then once a week. I use irrigations oftener only in acute cases of other types. The introduction of water or other liquids into the bowel, whether as an enema or irrigation, is an abnormal procedure, and cleaning out the whole colon too frequently may harmfully interrupt its normal functions. The colon receives a large amount of liquid material from the small intestine all day long, and expels a comparatively small amount of concentrated material only once or twice a day. Its chief physiologic functions are therefore retardation and absorption, and it secretes mucus. It is not a sewer and when the fecal contents are in the state of sewage an evacuation or irrigation is indicated. So far as mucus is concerned, an irrigation is indicated only for the abnormal thick membranes and strings of mucous colitis. The mere return of mucus, as reported by a nurse, does not of itself justify the repetition of the procedure. Indeed, overirrigation, like overcatharsis, may result in the production of much mucus. This is not, however, of the mucous colitis type. If given daily, irrigations remove an undue amount of nutritive material and interfere with the normal regulation of the bowels. Moreover, an irrigation may be a weakening and disturbing process for the patient. Therefore, irrigations are justified only by the value of their results and should be prescribed with the foregoing facts in mind.

In some circles there has been much criticism of the use of irrigations in mucous colitis, but I have been able to relieve many patients who have been denied the advantage of irrigations by physicians opposed to the procedure. When one sees the dirty gray, brown or blackish sheets, strings and rolled up wormlike masses of tough mucus with a rotten or dead-fish odor that are obtained by colon irrigations, one does not w [illegible] that these patients feel ill and that they obtain relief and show improvement as the result of the irrigation. In Europe, where the usual colon lavage consists of 2 liters of water or mineral water, administered once or twice a day, I have found a holy horror of the use of the large amounts of water employed in our irrigations. The doctors speak of them as "massive douches." But invariably when I have been able to induce a visiting European physician to watch one of my nurses give an irrigation and have studied the irrigation returns with him, he has been impressed with its value and in some instances has bought several sets of tubes for use at home.

Repeatedly when stool examinations have failed to suggest putrefaction or to show abnormal mucus, an irrigation has brought down putrid material or the characteristic colitis mucus. Thus a test irrigation is a diagnostic procedure. The microscope will also reveal the presence or absence of numerous leukocytes in the mucus, thus distinguishing the more inflammatory from the less inflammatory types. Irrigations are of value also in revealing departures from the prescribed diet.

Those who need irrigations must be distinguished from those who do not need them, for there are many persons, especially those with mucous colitis, who acquire the irrigation habit and resort to this measure whenever they become conscious of the lower part of the abdomen or feel what they describe as "toxic." They are encouraged in this attitude by the commercialized irrigation specialists, who are unduly numerous but do a thriving business. But this self-medication is just as reprehensible as any other self-medication and should be combated by the physician.

The method is not to be condemned because it is overused by exploiting nurses; but physicians are to be condemned who order frequent irrigations without specifications, who do not examine the character of the return, and who base their subsequent treatment of the patient on the usual perfunctory report of a nurse. It requires an intelligent, experienced and interested operator to observe properly and to assess correctly the character of the mucus and fecal matter and the significance of the sundry odors that are obtained at different times during the irrigation.

UNTOWARD REACTIONS

The untoward reactions are nausea with a feeling of pressure in the epigastric region; undue abdominal distention; cramps; anal irritation; and, following the irrigation, a feeling of weakness. The nausea is practically never sufficient to demand discontinuance of the irrigation. The distention is not uncommon with inexperienced nurses using the single tube method. Unless the bowel is filled with gas it can readily be governed by the operator. Cramps or colic may be associated with too rapid administration, the loosening of mucus, an undue amount of gas, the taking of a cathartic the night before, or an irritable colon. In the last case a painless and successful irrigation may usually be accomplished by the administration half an hour or an hour before the irrigation of a capsule containing codeine, 0.03 Gm. (½ grain), and atropine sulphate, 0.6 mg. (¹⁄₁₀₀ grain). In conditions of anal irritation, the irrigation may be preceded by a suppository containing ethyl aminobenzoate, 0.3 Gm. (5 grains), and the application of a 5 per cent ointment of ethyl aminobenzoate. In some cases the single tube is less irritating to the anal region than the double tube. The postirrigation weakness is minimized by a period of lying down with relaxation. However, most patients feel better after the irrigation than before.

MISHAPS AND DANGERS

The most common mishap reported is bleeding from the rectum. In examining these patients I have found that the blood usually comes from hemorrhoids, though occasionally from a fissure or ulcer. In two instances I have found a torn rectal valve and in several others an injured or severed polypus. On three occasions nurses have found in the return a "piece of flesh," which proved to be a detached polypus. These severe traumas resulted from the use of too stiff a tube or a tube with a sharp-edged terminal opening. Dr. J. M. Lynch tells me of perforation of a sigmoid diverticulum by the irrigation tube. In his advocacy of the large tube, Snyder states that "unless the greatest of care and skill is exercised during this manipulation an abrasion or perforation of the colon wall may readily result," though he fails to mention specific instances of either.

The charge that colitis or permanent dilatation of the bowel may result from irrigations has not been substantiated. In many roentgen studies Snyder did not find dilatation of the bowel in any patient, though many had been subjected to large numbers of irrigations at close intervals. In a study of the effects of enemas, Soper found the rectal tone improved.[1]

SUMMARY

I have been considering the methods of administration, the therapeutic application, the abuse, and the dangers of repeated or routine colon irrigations. These are employed in chronic states of the bowel, such as are encountered in mucous colitis, intestinal putrefactive toxemia and in cases in which a focus of infection is believed to reside in the bowel, as in certain cases of rheumatism, neuritis, secondary anemia and sundry run-down conditions. There are many other acute and chronic conditions in which an irrigation may be found useful, but of these I have omitted discussion.

In recapitulation: 1. A colon irrigation is a process of lavage to be distinguished from an enema. 2. It is given to dilute and wash out the contents of the bowel above the normal defecation area, to soften and loosen abnormal mucus and to lavage the colon wall. 3. It leaves the colon more or less empty and contracted and thus exerts a beneficial effect on its blood supply and its tone. 4. It should be preceded by defecation and should be administered very slowly and without much pressure. 5. The one tube and two tube methods are employed, the tubes being inserted not more than 6 inches. 6. The high insertion of a large rather stiff tube is dangerous and without proved advantage. 7. The dangers of the stiffer tube are perforation, injury to a polypus, tearing of a rectal valve, and abrasion of the wall. 8. The charges that irrigations do harm by removing normal mucus, by lowering the tone of the bowel and by producing colitis are without foundation. 9. An irrigation is frequently a failure in the hospital ward and in the hands of the unspecialized nurse.

I trust that my warnings against its improper administration, its dangers and its abuse will not discourage physicians in the proper utilization of this valuable therapeutic measure.

HYGEIA PURE STRAINED CARROTS

Contains Vitamin D

Added Irradiated Ergosterol (Mildly seasoned with salt)

Manufacturer.—Snider Packing Corporation, Rochester, N. Y.

Distributor.—Hygeia Nursing Bottle Company, Buffalo, N. Y.

Description.—Strained carrots retaining in large measure the mineral and vitamin content of the raw carrots used; with added vitamin D (irradiated ergosterol), 60 D units per fluidounce; packed in jars. The D units are those defined by the Council on Pharmacy and Chemistry of the American Medical Association (New and Nonofficial Remedies, 1931, p. 414). One fluidounce is equivalent in vitamin D to the D content of one teaspoonful of cod liver oil. Mildly seasoned with salt.

Manufacture.—The carrots are purchased locally and graded for size and the larger carrots used. The carrots are steamed to facilitate the removal of the skins and then mechanically peeled. The peeled carrots are inspected, further trimmed if necessary, diced, filled into No. 10 cans and a hot brine solution (87 C.) is added. The cans are sealed and processed for forty-five minutes at 115 C.

The canned carrots in the preparation for puréeing are treated essentially as described for Strained Peas. The liquid content of the can is strained off and not used for puréeing, which eliminates most of the salt. The processing is that described for the Strained Peas. Irradiated ergosterol is incorporated in the product, as described for Strained Peas.

Analysis (submitted by manufacturer).—

Specific gravity 20 C./20 C	1.03
	per cent
Moisture	93.9
Total solids	6.1
Ash	0.7
Fat (ether extract)	0.2
Protein (N × 6.25)	0.6
Reducing sugars after inversion as dextrose	2.6
Starch (acid hydrolysis method)	0.4
Crude fiber	0.6
Carbohydrates other than crude fiber (by difference)	4.0
Calcium (Ca)	0.03
Iron (Fe)	0 001
Phosphorus (P)	0.01

Calorics.—0.2 per gram; 6 per ounce.

Vitamins and Claims of Manufacturer.—See these sections for Strained Peas (The Journal, Feb. 13, 1932, p. 555).

U-COP-CO GELATINES

(Flaked and Granulated)

Manufacturer.—United Chemical and Organic Products Company, Chicago.

Description.—Granular and flake plain unsweetened gelatin; graded on the basis of jelly strength for special uses.

Manufacture.—U-Cop-Co Gelatine is made entirely from porkskin trimmings and "osseine" prepared from packer bone, from animals slaughtered solely for human consumption under the supervision of government inspectors. The fresh skins are frozen and stored under refrigeration until used. The stock drawn from refrigeration is washed and thawed in running water. Arsenic free hydrochloric acid is added to "plump" the stock and prepare it for cooking. The acid is neutralized and washed out. The stock is placed in cooking tanks and extracted by successive additions of hot distilled water. The separate gelatin solution extracts are clarified by passing through aluminum presses containing activated carbon and a diatomaceous "filter aid,"

For the granulated gelatin the clarified liquor is jelled on a rubber belt which passes through a refrigerated tunnel. The jelly is mechanically deposited on aluminum netting, dried by warm filtered air, and the dried gelatin is milled to a suitable granulation.

For the flake gelatin the clarified liquor flows on a large rotating wheel the surface of which is maintained by steam at a temperature above 100 C. The gelatin liquor is dried during one rotation of the wheel in approximately one minute. The dry film is scraped from the wheel by knives and the resulting flakes are broken up in a mill.

For certain special purposes, U-Cop-Co Gelatine is made from "osseine" prepared from edible packer bone. The bone is ground, the fat is extracted with light gasoline and the mineral matter with dilute hydrochloric acid. The organic residue or "osseine" is prepared for cooking by steeping in dilute lime water for three or four weeks. The lime is removed by the addition of dilute hydrochloric acid and washing in water. The subsequent washing, cooking and other treatments are substantially the same as described for the "porkskin" trimmings.

The different granular and flake gelatin grades intended for special uses are prepared by blending in definite proportions the gelatin from the several extractions, which respectively have different properties in jelly strength, viscosity, clearness, melting point, etc. These different properties adapt the various grades for particular uses.

All possible precautions are observed to prevent bacterial contamination of the gelatin. The equipment is thoroughly cleaned between runs. All pipe lines are either aluminum or nickel. Storage tanks for the gelatin liquor are glass lined. All operations are under laboratory control. Each lot of gelatin is separately tested.

Analysis (submitted by manufacturer).—

	per cent
Moisture	10.0
Ash (approximately 80 per cent sodium chloride)	1.2
Fat (ether extract)	0.0
Protein (N × 5.55)	88.5
Carbohydrates	0.0

Jelly strength of different grades (Method of the Edible Gelatin Manufacturers Research Society of America)......50 to 275 Bloom

	(parts per million)
Arsenic (As)	0
Copper (Cu)	less than 5
Zinc (Zn)	less than 5
Lead (Pb)	0
Sulphur dioxide (SO_2)	0
Added preservatives	none

Calorics.—3.5 per gram; 99 per ounce.

Micro-Organisms.—The manufacturer guarantees absence of Bacillus coli, liquefying and gas forming bacteria and pathogenic organisms.

Claims of Manufacturer.—U-Cop-Co Gelatines may be used in a wide variety of desserts, candies, salads, marshmallows, ice cream, jellied meats and other recipes and are valuable for many special diets.

FREIHOFER'S 100 PER CENT WHOLE WHEAT BREAD

Manufacturer.—The Freihofer Baking Company, Philadelphia.

Description.—A whole wheat bread made by the straight dough method.

Manufacture.—The dough ingredients, a mixture of whole wheat flour, water, salt, sucrose, lard, vinegar, yeast and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate, are mixed in a high speed mixer. The dough is fermented for about one and three-quarter hours, is folded, fermented twenty minutes, folded, fermented fifteen minutes, divided, molded, panned, baked about forty minutes, cooled, and wrapped in wax-paper. The factory, equipment and storage rooms for the materials used are kept in strictly sanitary condition.

Analysis (submitted by manufacturer).—

	per cent
Moisture (entire loaf)	36.8
Ash	2.1
Fat (acid hydrolysis method)	2.2
Protein (N × 6.25)	10.5
Crude fiber	1.6
Carbohydrates other than crude fiber (by difference)	46.8

Calories.—2.5 per gram; 71 per ounce.

Claims of Manufacturer.—A bread of good quality.

THE TESTICULAR HORMONE

Experimental and clinical evidence, as well as numerous studies of transplantations, indicates clearly that the testes possess one or more endocrine functions. The experimental evidence of the presence of an internal secretion of the testes has been based primarily on the effects observed on the removal of the testes. Although it has been stated from time to time that extracts of testicular tissue when injected into castrated animals produce various effects, many of which are associated with secondary sex characters, most workers in endocrinology have not accepted these statements because the criteria used for determining the effects of the extracts on castrated animals were of doubtful value. Probably the first report giving clear cut evidence of extracting and fractionating the hormone from testis tissue was given by McGee,[1] who obtained a lipin fraction from bull's testis which, when injected intramuscularly into brown leghorn capons, caused a remarkable growth of the comb, wattles and ear lobes. The response is prompt, increase in the size of the comb can be observed in from one to three days after the injection, and when the injections are discontinued the regression of the comb to the capon type takes place rapidly.

Most extensive studies of the action of the testicular hormone have been made by Moore[2] and his co-workers. He has developed several different mammalian tests for the presence of the hormone. The foundations for the criteria used in the mammalian tests were laid by the earlier studies of Moore and his students on the various effects observed as the result of castration of the rat and the guinea-pig. Earlier observations by Moore and Benoit[3] showed that the intact testis in situ or a cryptorchid testis prolongs the time of motility of the spermatozoa found in the epididymis. In the case of the completely castrated guinea-pig with the epididymis left intact, the spermatozoa never retained their motility beyond twenty-three to twenty-five days following castration, but by injection of the testis extract into the guinea-pig the time of motility of the spermatozoa was distinctly prolonged, the longest time being fifty-four days. The second mammalian test for the presence and action of the testicular hormone is the electrical ejaculation test. This test, originally discovered by Batelli in 1922, consists in causing the animal to ejaculate semen by an electrical stimulus through the brain. A normal guinea-pig if thus tested once a week yields a secretion of from 1.5 to 2 Gm. The material consists of secretions from the prostate and seminal vesicles and is distinctly fluid as ejaculated, but it soon coagulates to a firm jelly as a result of the coagulating enzymes present in the prostatic secretion. In the guinea-pig several weeks after castration these secretions are no longer normal; the result is that little or no material is ejaculated when the test is applied, and whatever material is secreted is exceedingly small and does not coagulate. Moore and Gallagher[4] have shown that if a castrated guinea-pig is injected with the testicular extract the loss of secretory function of both the seminal vesicles and the prostate can be corrected in that the secretion is near to the normal in amount and possesses the normal characteristics of the fluid. They have even taken an adult guinea-pig which has been castrated for six months and in which the ejaculation test had been found negative for some time and after from ten to fourteen daily injections of the extract obtained a normal ejaculation. The third mammalian test applied by Moore, Price and Gallagher[5] is that of the testis control on the cells of the prostate. In the castrated animal the entire prostate usually diminishes appreciably in size and rapidly shows striking degenerative and atrophic changes. These workers have shown that they can maintain the normal conditions of the cells of the prostate by daily injections of the hormone into the castrated animal. They have, in fact, stimulated the development of an apparently normal adult prostate in a prepubertally castrated rat 100 days old.

The fourth mammalian test applied by Moore, Hughes and Gallagher[6] is that of the testis control on the cells of the seminal vesicles of the rat. Here again it is now well known that the size and the cells of the seminal vesicles are controlled by the testes. In castrated animals, both of these are restored to the normal picture by the daily injections of the hormone. The same authors have also stimulated the production of the histologically normal adult seminal vesicle in the prepubertally castrated rat by injections of the hormone.

The studies thus far seem to indicate that from a qualitative point of view the comb growth reaction and the mammalian cytologic tests are of about the same order of delicacy. The spermatozoa motility test is approximately ten times as sensitive as the comb growth method, and the ejaculation test is the least delicate of all.

After this substance had been found in bull's testis, it was deemed important to determine that the substance is specifically present in testicular tissue and not possibly a general extractive that may be found in various tissues. Thus far this substance has been found in bull calf, embryonic calf and hog testicles. Gallagher[7] examined other bull tissues and found the hormone in only one other organ, the epididymis. He repeatedly obtained negative results from bull blood, although recently Womack and Koch[8] obtained evidence of its presence when the equivalent to that obtainable from 600 cc. of bull blood was injected into capons daily. Loewe and Voss,[9] as well as Funk, Harrow and Lejwa,[10] found it in human male urine. Womack and Koch have also found the hormone in adult male and female urine but not in the urine from boys under 10 years of age. The source of the hormone in adult female urine is a mystery. Loewe and his co-workers also report detecting the hormone in the male blossoms of Salix caprea.

It at once became apparent to these workers that in order to make progress in the purification of this extract it would be necessary to have a quantitative method for determining the amount; and as there are at present no chemical methods of measuring it, biologic effects for assay must be used. Thus far the quantitative assay of preparations of testicular hormone has been limited to comb growth and seminal vesicle tests. Gallagher and Koch[11] have studied the former reaction in detail and conclude that the increase in comb size is a reliable quantitative criterion provided the growth is obtained in five days, is the average from five birds, and as expressed in increase in length plus increase in height is from 3 to 7 mm. and preferably 4 to 6 mm. They define their bird unit as the amount of hormone which, when injected intramuscularly daily for five days, causes an average of 5 mm. in the sum of the increase in length and height of the comb of at least five brown leghorn capons. Womack, Koch, Domm and Juhn[12] recently showed that the growth response to a given dose of the hormone in the capon is influenced by the amount of light to which the bird is exposed.

The mammalian tests are at present not as suitable for quantitative assays as the comb growth method. The rat unit of the male hormone as determined by Moore and his co-workers[13] is defined as the minimal daily amount required to maintain 50 per cent of castrated animals in a normal condition, the index being normal prostate and seminal vesicle. Twenty days after castration has proved to be sufficient time for the injections to express their true potency.

While the exact chemical nature of the hormone is not known, some of the chemical properties have been determined. It is found in the lipoid fraction and in general can be fractionated by methods similar to those employed for the female sex hormones. The material is resistant to temperature, acids, alkalis and oxygen. The yield of the hormone is exceedingly low. In the earlier studies it was necessary to inject the equivalent of from one-half to one pound of testicular tissue to make an assay on the capon. With better methods of comb measurement and further purification of material, effects are observed from injections representing much less original tissue. The most active and probably purest preparation thus far obtained is one in which a dose of 0.01 mg. of the active material per capon daily causes distinct comb growth. The product acts best when injected subcutaneously or intramuscularly; the dose for action by mouth is at least ten times as high.

In the light of the results obtained on animals, it is reasonable to suppose that similar results will hold with reference to man. Thus far there has been no indication that the product can be of any value in restoring "vigor" to the aged or neurasthenic. However, if there is an indication for its use and if the dosage in man is comparable to that effective in the capon, the daily injection for a man weighing 150 pounds would have to be an amount equivalent to 5 pounds of bull's testis or 2 gallons of normal male urine. If taken by mouth, the dosage presumably would have to be much larger. These deductions, based on animal experimentation, indicate the probable fallacy of prescribing testis preparations to man.

DIET AND THE PRODUCTION OF HUMAN MILK

There has never been a time, perhaps, when so much thought and enthusiasm have been concentrated on the problems of infancy and childhood as at present. The recent White House Conference on Child Health and Protection, called by President Hoover, represented the results of months of careful deliberation by many experts from all parts of the country. The chairman of the conference, Dr. Ray Lyman Wilbur,[1] has pointed out that we have injected so many artificial conditions into our industrial civilization that the old normal relationships of mother and child, child and family, family and neighborhood, have been changed. There is now a much less direct struggle with nature and its immediate forces than has ever been the situation before in our country. We have softened this struggle for man, Wilbur adds, by all forms of protection—better houses, better clothing, more and better food supplies, preventive medicine, and better medicine and sanitation in general. All of this has called for a delegation of functions, once performed by the individual in the home, to all sorts of outside dependence.

[1] White House Conference, 1930, New York, Century Company, 1931.

There is a period of life, in infancy, when the rôle of the mother is unquestionably paramount in that she supplies through her maternal tissues the nutrition of her young. The words of Mrs. Rose[2] "Happy the baby who enjoys his inalienable right of Nature's food supply—his own mother's milk" constitute a slogan worth frequent repetition. Modern investigation is disclosing in increasing measure that even mother's milk is susceptible to marked variations. The human mother, like other lactating individuals, is subject to the influence of her own diet, which may be reflected to some extent in the composition of her milk. One cannot study the elaborate investigations of Macy and her co-workers in Detroit[3] without realizing that even human milk is a variable to an extent that must have some varying effects on the young that are dependent on it. In a study made by Hoobler[4] in Detroit in 1917 he reached the conclusion that different types of protein in the maternal ration unmistakably influence the milk produced. Broadly speaking, he maintained that diets rich in proteins, particularly those of animal origin, are beneficial. He insisted that it was not easy to keep human lactating mothers in positive nitrogen balance on diets in which the protein was derived exclusively from vegetable sources. There is always the danger that a mother will "milk the flesh off her back" in the production of her breast milk.

Investigation of the problems of the effect of diet on human milk secretion involves personal difficulties of obvious sorts. It is laborious, and progress will inevitably be slow. Physiology is therefore compelled to consider the contributions to our knowledge that can be made by other species than man. There is an elaborate literature on the mammary secretion of cattle; but the conditions that refer to these vegetarian ruminants are not always applicable to mankind. A recent writer,[5] referring to cows and goats, recalls that they are the result of several centuries of intensive breeding and that the capacity of the mammary gland, and probably their entire metabolism, has been so specialized that we are not able to make direct comparisons of the results in these animals with those on other animals and on human beings, wherein the process of milk secretion has not been so highly developed. Working at the University of Rochester, N. Y., Daggs[5] has investigated the mammary functions of dogs. Balanced diets were fed during the period of lactation, the only variable being the source of the protein. The results indicate that there are conditions in which a degree of betterment in lactation can be brought about by changing the dietary protein. For example, in these experiments liver was a much better source of protein for lactation than either egg or round steak. In fact, his conclusion that liver is the best source of protein (of those tried) for milk production in dogs is borne out by the quantity of milk produced, the fat content of the milk, the nitrogen retention, and the slope of the growth curve of the pups. As far as human experience is concerned, it matters not so much what proteins or dietary factor may for the moment be emphasized in the progress of investigation. The feature of moment is that the problems of human lactation call for extensive research at the earliest opportunity to insure that the "inalienable rights" of the nursling shall be safeguarded by the prepared intelligence of those to whom the responsibility for human well being is entrusted.

Current Comment

CALCIUM AND HYPERCALCEMIA

Ever since the discovery that irradiated ergosterol (viosterol) can affect the metabolism of calcium and phosphorus in the body, interest has centered in the mechanism by which the characteristic changes are brought about. Closely related to this problem are the toxic manifestations that can be produced by enormous doses of viosterol. It was early established that this substance can be made to mobilize calcium in such a way as to induce a condition of hypercalcemia. The question arose, therefore, as to whether this condition is due to an enhanced absorption of calcium from the food sources in the alimentary tract or whether the alkali earth is drawn from depots within the organs and tissues. The replies have been contradictory until quite recently. Now, however, a harmony of opinion seems to have been attained. Two independent groups of investigators[1] have demonstrated that hypercalcemia can be brought about, even in the almost complete absence of calcium from the diet, by giving sufficiently large doses of viosterol. As Hess[1] has pointed out, the failure of investigators to bring about this condition and their conclusion that the source of the excess calcium in this form of hypercalcemia is the food and not the tissues is due to the fact that viosterol was given in insufficient amounts. The immediate source of the calcium under the admittedly extreme conditions cited is in the bones, the great storehouse of the element in the body. Hypercalcemia in experimental animals was greatly reduced by intravenous injections of a solution of sodium bicarbonate. Following reduction by such means, a marked excess of calcium and phosphorus was found in the lungs and the kidneys. These investigations represent extreme conditions so far as the overdosage with viosterol is concerned; nevertheless, they indicate how drafts may be made on the inorganic storehouse of the bones in times of stress. When an abundance of dietary calcium is available under conditions that can favor its ready absorption, the results of hypercalcemia are far less drastic.

EXERCISE AND THE VITAMIN B REQUIREMENT

Few scientific questions in relation to nutrition are of greater interest at present than those relating to the functional rôles of the vitamins. How do these indispensable food factors act in the body, or what specific purposes do they serve? For some of the vitamins the answers seem to be clarifying. In the case of vitamin A, for example, its importance for the maintenance of a perfect nutritive status in some of the epithelial tissues of the body has been well established. When there is lack of the essential substance for any considerable period, keratinization of certain epitheliums inevitably ensues. In view of the stimulating effect of vitamin B on appetite, some of the earlier students of the subject assumed the existence of a relationship between this vitamin and the secretory functions of various glands; but experiment has not substantiated this view. More compelling have been the attempts to connect vitamin B with metabolism, though the actual possible relationships are by no means clear at present. Reviewing the animal investigations of recent years, Sherman and Smith[1] conclude that a pronounced deficiency in vitamin B is followed by failure of appetite, decreased food consumption, and finally starvation, resulting in gastric and intestinal atony, fall of body temperature and death. A serious deficiency of vitamin B in human nutrition, these authors add, will lead to beriberi or, under less drastic conditions, to failure of appetite, possibly minor digestive disturbances, and loss of stamina. In a recent study at Yale University by Cowgill and his collaborators,[2] comparisons were made between the vitamin requirement of resting animals and those of muscular activity. Advantage was taken of the now well demonstrated fact that the capacity for storage of vitamin B in the body is rather limited. In each case of increased exercise the period required for the development of the anorexia characteristic of lack of the vitamin B complex was markedly less than the time required when forced exercise was not given. These observations are considered to support the interpretation that the vitamin B requirement per unit of tissue mass is proportional to the metabolism of that mass. These results also support the observations of other investigators showing a relationship between vitamin B and metabolism. The observations do not solve the question of the possible relation of vitamin B to the metabolism of any particular nutrient.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Monday from 12 noon to 12:05 p. m., over Station WBBM (770 kilocycles, or 389.4 meters) and other stations of the Columbia Broadcasting System, and on Wednesday and Friday from 2:25 to 2:30 p. m., over Station WBBM, Chicago.

The program for the week is as follows:

February 29. Running Water is Not Always Pure.
March 2. First Aid.
March 4. Accidents and Tuberculosis.

There is also a fifteen minute health talk sponsored by the Association on Saturday from 11:15 to 11:30 a. m.

The program for the week is as follows:

March 5. How Mothers Can Help Prevent the Spread of Contagion in School.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Sale of "Koremlu" Forbidden.—Dr. Jacob C. Geiger, director of public health of San Francisco, recently issued an executive order which forbids in that city the sale of Koremlu, a depilatory containing thallium acetate. This action followed a conference of a number of dermatologists practicing in San Francisco and the publication in THE JOURNAL of articles referring to Koremlu. Three cases of retrobulbar neuritis, ascribed to this depilatory, were reported by Dr. William Mahoney, Boston, in THE JOURNAL, February 20, p. 618.

Survey of Typhoid Carriers.—Drs. Arthur Hieronymus and Ralph W. Sanders, health officers of Oakland and Alameda, respectively, recently completed surveys of known typhoid carriers residing in the two cities. Specimens were obtained from all carriers and examinations were made in laboratories to determine whether such individuals are still carriers. Information relative to the compliance of the carriers with regulations for their control was also obtained. It is planned to make similar surveys at least twice each year, according to the bulletin of the state department of health.

Lectures at University.—Dr. Henry E. Sigerist, director, Institute of the History of Medicine, University of Leipzig, Leipzig, Germany, gave three lectures under the auspices of the University of California Medical School. Two of these lectures, "The Evolution of Medical Ethics," January 19, and "Medicine of the Renaissance," January 22, were given in San Francisco, and the third, "Civilization and Disease," January 20, was given in Berkeley. Dr. Willis C. Campbell, professor of orthopedic surgery, University of Tennessee School of Medicine, Memphis, addressed the faculty and students of the medical school, January 23, on "Treatment of Ununited Fractures."

Society News.—At a joint meeting of the Los Angeles County Medical Association and the Los Angeles County Heart Association, February 18, the speakers included Drs. John C. Ruddock and Arthur S. Granger, Los Angeles, on "Treatment of Thyroid Heart Disease" and "Use and Value of Drugs in Heart Disease," respectively. Dr. C. Frederic Fluhmann, San Francisco, addressed a joint meeting of the San Fernando Valley Branch of the county medical society and the Hollywood Academy of Medicine, February 25, on sex hormones in the study of pelvic disease.——Dr. Johannes M. Nielsen addressed the Los Angeles Society of Neurology and Psychiatry, February 24, on "Progressive Spinal Muscular Atrophy."——Dr. Loyal Davis, Chicago, addressed the San Diego County Medical Society, February 9, on "Effects of Various Diagnostic and Therapeutic Solutions on the Spinal Cord and Its Membranes."

CONNECTICUT

Standard Forms for Registration of Births and Deaths.—The bureau of vital statistics, January 1, adopted standard forms for the registration of births and deaths for the use of registrars of the state in accordance with the action of the public health council of the Connecticut Department of Health. This system will aid in the compilation of comparable statistics from state to state and will assist the federal government in compiling uniform statistics for the nation.

Low Mortality Rate.—Connecticut maintained the same low death rate (10.5) in 1931 that it recorded in 1930. The infant mortality rate of 53.9 deaths of infants under 1 year of age per thousand live births is a record low rate. The lowest rate (0.9) in the history of the state was noted for diphtheria. The tuberculosis death rate for all forms (54) is also a record death rate, as is the rate of 73.7 for all the pneumonias. The maternal mortality rate (4.7 per thousand living births) is the lowest rate to appear in the records of the state.

GEORGIA

Society News.—Dr. Thomas P. Goodwyn, Atlanta, addressed the Fulton County Medical Society, Atlanta, Dec. 3, 1931, on "Fractures of the Upper End of the Tibia Involving the Articular Surfaces." The program of the society, January 21, included a paper by Dr. Dunbar Roy on "Some Practical Points in Refraction Based on the Histories of Eighteen Thousand Cases." Dr. Olin S. Cofer spoke, February 4, on "Treatment of Prolapse of the Uterus."——Dr. Roger W. Dickson presented a case of Hirschsprung's disease before the Fulton County Pediatric Society, February 11.——Dr. Robert A. Berry, Americus, has resigned as health officer of Sumter County, it is reported, to enter private practice at Piedmont, S. C.

ILLINOIS

Society News.—The Peoria City Medical Society was addressed, February 11, by Drs. Raymond W. McNealy on "Recent Advances on the Treatment of Fractures"; Samuel J. Fogelson and Arthur J. Atkinson, "Mucin Therapy in Gastric and Duodenal Ulcer," and Charles A. Elliott and M. Herbert Barker, all of Chicago, "Modern Conception of Renal Disease."——At the meeting of the Ogle County Medical Society, Rochelle, January 14, Drs. Chester C. Guy and LeRoy H. Sloan, Chicago, spoke on "Common Surgical Mistakes as Seen by the Pathologist" and "Differential Diagnosis of Substernal Pain," respectively.——Dr. Drew W. Luten, St. Louis, addressed the St. Clair County Medical Society, East St. Louis, February 4, on "Coronary Sclerosis."

Increase in Immunization Work.—According to the state health director, the volume of "preventive practice" in relation to the prevalence of certain diseases subject to control through vaccination and diagnosis by laboratory procedure increased in Illinois during 1931. The amount of toxoid and toxin-antitoxin distributed by the department indicates that twenty-one children were immunized against diphtheria for each case reported in 1931, against sixteen to one in 1930, and eleven to one in 1929. For each case of smallpox fifty-four persons were vaccinated in 1931 compared with fifteen per case in 1930 and twenty-one per case in 1929. Against typhoid, twenty people were vaccinated per case in 1931 compared with twenty-one per case in 1930 and twelve per case in 1929. The diagnostic laboratories of the department of health examined for typhoid thirteen specimens per case reported in 1931 compared with 9.5 per case in 1930. For diphtheria there were 2.5 specimens per case examined in 1931 compared with 1.4 per case in 1930. The rate for tuberculosis was 1.5 specimens per case in 1931 and 1.4 in 1930. For these three diseases 40,155 specimens were examined during 1931 against 35,984 in 1930, although the aggregate number of cases reported declined from 18,997 to 16,667.

Chicago

Search for Precocious Students.—Northwestern University is conducting a search for precocious students who meet all university requirements but who are from 13 to 15 years of age. The announcement states that while the problem of what to do with the precocious child after graduation from high school is recognized, no university has attempted to approach the problem by evolving a special program for such students. By precocious, it was pointed out, is implied an intelligence quotient of more than 130 or such youthful attainments as were characteristic of Jeremy Bentham, who wrote Greek and Latin at the age of 5 and prepared to enter Oxford at 10; Benjamin Franklin, publisher of a newspaper at 17, and George Washington, a professional surveyor at 15. Special provisions will be made to meet the needs of the superior students at Northwestern. There are two such students in the school at present, but it is felt that they have lacked an adequate environment. It is planned to offer this environment to the students next year. Of the four precocious students who have entered the university, one is the author of several novels and many short stories and is now editor of two magazines, and one recently was awarded a Rhodes scholarship to Oxford University. A letter has been sent to a selected list of high school principals apprising them of Northwestern's desire to aid the precocious student.

INDIANA

Personal.—By the will of the late Dr. Daniel L. Miller, Goshen, $4,000 is to be invested in securities, the income to be used for twenty years in providing Christmas dinner for needy children, after which the principal will go to Goshen Hospital for paying hospital expenses of poor persons.——Josiah K. Lilly, Sr., president of Eli Lilly and Company for thirty-four years, will retire as president, it has been announced. During the World War, the firm outfitted a base hospital corps for service, Mr. Lilly personally contributing $15,000 to this project.

Graduate Course.—A graduate course in otolaryngology will be given at Indiana University School of Medicine, Indianapolis, April 18-30. The course, which will be under the supervision of Dr. John F. Barnhill, will be supplemented by clinical demonstrations and operations during the morning hours. Time will be spent in the anatomic laboratories in the afternoon and evening. Completion of the course will give a total of eighty-four hours of anatomic study and thirty-six hours of clinical instruction and observation. The fee for the course will be $75, which covers the cost of anatomic material. Further information may be had from Dr. Willis D. Gatch, acting dean of the medical school.

Society News.—At the meeting of the Tri-County Medical Society in Columbus, Dec. 17, 1931, Dr. John W. Carmack, Indianapolis, spoke on "Upper Respiratory Infections."——Dr. George A. May, Madison, addressed the Jefferson County Medical Society, January 25, on acidosis.——The Wabash County Medical Society, North Manchester, heard Dr. Louis A. Sandoz, South Bend, discuss skin disease, January 7.——The Elkhart County Medical Association was addressed, January 7, by Dr. Charles O. McCormick, Indianapolis, on "Rectal Ether Analgesia in Obstetrics."——A symposium on prostatic diseases was conducted before the Cass County Medical Society at Logansport, January 22.——The Jackson County Medical Society was addressed at Seymour, January 7, by Dr. Frank M. Gastineau, Indianapolis, on "Some Phases of Syphilis."——The Wells County Medical Society was addressed at Bluffton, February 2, by Drs. William O. McBride and Juan Rodriguez, Fort Wayne, on "Sinus and Middle Ear Infection."——Dr. Hiram E. Ross, Danville, Ill., addressed the Fountain-Warren Medical Society at Williamsport, February 4, on "Skull Fractures—Early Care and Treatment."——At a meeting of the Huntington County Medical Society, February 2, Dr. Lloyd L. Ely, Indianapolis, spoke on "Diabetic Diets."——The Daviess-Martin Medical Society was addressed, January 26, by Dr. Robert G. Moore, Vincennes, on "Observations of Chronic Diseases of the Chest."——Dr. Louis H. Clerf, Philadelphia, addressed the Tippecanoe County Medical Society, February 11, on "Bronchoscopic Aid in the Diagnosis and Treatment of Pulmonary Diseases."

KENTUCKY

Society News.—The Jefferson County Medical Society was addressed, February 15, by Drs. William L. Sneed and James J. King, New York, on "Treatment of Delayed Union in Fractures and of Ununited Fractures" and "Treatment of Brain Abscess," respectively.——Dr. Milton W. Williamson, Atlanta, Ga., has been appointed health officer of Green County to succeed Dr. Agnes M. C. Locke, Greensburg, resigned.——Drs. Leslie H. Winans and Samuel C. Smith addressed the Boyd County Medical Society, Ashland, February 1, on diseases of the chest and diseases of the kidney, respectively.

Illness Among School Children.—Forty children, two teachers and the janitor at the Snyder School, Owensboro, became ill within twelve hours recently, with nausea, vomiting and diarrhea as symptoms. The investigation disclosed that only part of the sick children had eaten the lunch served at school. Analysis of the water showed some Bacillus coli present, but of insufficient quantity to cause the illness. According to Dr. George L. Thompson, Owensboro, director, Daviess County Health Department, February 16, the investigation indicated the illness may have been caused by gas from the school furnace.

Bills Introduced.—H. 604 proposes to reduce to not more than $10 the annual occupational tax required of physicians, surgeons or dentists in cities of the first class. H. 633 proposes to make it unlawful for any person habitually to use morphine, cocaine, eucaine, heroin, or other derivatives of opium or coca leaves, except as prescribed by a licensed physician in the course of treatment. H. 634 proposes to make it unlawful for any person to possess, sell, manufacture or distribute in any other than its natural state any marihuana, Indian hemp or hasheesh, "except under the direction and in the course of treatment by a licensed physician."

MARYLAND

Society News.—The Johns Hopkins Medical Historical Club was addressed, February 15, by Col. Fielding H. Garrison on "The Children of Robert and Clara Schumann: A Study in Family History," and Dr. Lewellys F. Barker, Baltimore, "Medicine in Soviet Russia."——Dr. Arthur M. Shipley, Baltimore, discussed the film "Traumatic Surgery of the Extremities," which was shown before the Baltimore County Medical Society, February 17.

Personal.—Roscoe Raymond Hyde, Ph.D., has been appointed professor of immunology at the School of Hygiene and Public Health, Johns Hopkins University, Baltimore. The position was left vacant last May by the death of Dr. Carroll G. Bull. Dr. Hyde has been connected with the School of Hygiene and Public Health since its beginning in 1918 and was associated with Dr. Bull as senior associate in immunology until 1928, when he took over the work of the department of filtrable viruses.——Dr. Joseph Pokorny, connected with the Baltimore City Health Department, has been appointed coroner at large and assigned to the investigation of automobile fatalities.

MASSACHUSETTS

Bill Enacted.—S. 35, approved by the governor, February 8, has been enacted as Chapter 8, Laws of 1932. The new law amends the prior law with respect to the necessary qualifications for membership on the Board of Registration in Medicine by requiring members to be registered as qualified physicians under the Massachusetts law and omitting the provisions of the prior law specifically stating that members be graduates of a legally chartered medical college or university.

Society News.—At the third annual meeting of the New England Obstetrical and Gynecological Society in Boston, Dec. 2, 1931, Dr. Edward S. Brackett, Providence, R. I., was elected president, and Dr. Joseph W. O'Connor, Worcester, secretary.——Dr. Homer F. Swift, New York, addressed the New England Pediatric Society, Dec. 11, 1931, on "Recent Progress in Research Work in Connection with Rheumatic Fever."——A joint meeting of the Greater Boston Medical Society and the Beth Israel Hospital was addressed, Dec. 9, 1931, by Drs. Moses Swick, New York, on "Intravenous Urography as a Diagnostic Aid," and Ernest Granville Crabtree, "Practical Applications of Intravenous Urography."——Dr. Thomas F. O'Brien, Worcester, addressed the Webster-Dudley Medical Club in Webster, Dec. 16, 1931, on "Conduct of Normal Labor."——Dr. John F. Fulton, Jr., New Haven, Conn., addressed the Harvard Medical Society, Dec. 8, 1931, on "Evolution of the Babinski as Illustrated in the Monkey, Baboon and Chimpanzee."——Michael M. Davis, Ph.D., Chicago, addressed a joint meeting of the Boston Medical Library and the Suffolk District Medical Society, January 27, on "Paying Your Sickness Bills."——The Norfolk District Medical Society was addressed, January 26, by Drs. Frederick W. O'Brien on "Natural and Artificial Light in the Treatment of Tuberculosis"; Albert Ehrenfried, "Artificial Pneumothorax and Phrenicectomy," and Samuel C. Cline, "Nose and Throat Conditions in Tuberculosis."

MICHIGAN

Orthopedic Association Organized.—The Orthopedic Association of Michigan was recently established, principally for the purpose of cooperating with the State Commission for Crippled Children in the care of indigent cripples from all parts of the state. Provision has been made in the association for associate members who must have had some training in orthopedic surgery but who do not necessarily devote their full time to this specialty. Their function is to cooperate in the after-care of the cripples, but they are not yet allowed to carry out any operative procedures, according to the *Journal of Bone and Joint Surgery*. The group of physicians who organized the association are Drs. Carl E. Badgley, William E. Blodgett, Frank E. Curtis, Robert V. Funston, Angus G. Goetz, Frederick C. Kidner, Alfred D. La Ferté, Charles W. Peabody, Frank H. Purcell, Daniel M. Stiefel, Detroit, Vernon L. Hart, Ann Arbor, and John T. Hodgen, Grand Rapids.

Dr. Clark Honored.—Dr. John E. Clark, Detroit, was guest of honor at a luncheon given by the "Seniors Club" of the Wayne County Medical Society, February 12, in the society's new home. Dr. Clark has been county chemist for thirty-five years. He joined the Wayne County Medical Society in 1878 and is the oldest living member. The tribute to Dr. Clark was in recognition of his contribution to the health of the community during the past half century, as well as for his untiring efforts to aid organized medicine in Michigan. Dr. Louis J. Hirschman was toastmaster at the luncheon, which was attended by seventy-three physicians. Dr. Harry W. Plaggemeyer, president of the Wayne County Medical Society, presented a life membership to Dr. Clark. The speakers included Dr. Oscar S. Armstrong, who graduated with Dr. Clark from the University of Michigan Medical School, 1877, and Dr. Walter J. Cree, who is Dr. Clark's oldest living student.

MINNESOTA

Chiropractor Sentenced.—Frederick I. Sheldon, Minneapolis, licensed chiropractor, pleaded guilty, February 2, to a charge of practicing medicine without a license. Sheldon was sentenced by Judge Reed of the district court to a term of three months in the Minneapolis workhouse. The sentence was stayed for one year.

Society News.—Dr. William W. Duke, Kansas City, Mo., will address the Hennepin County Medical Society, Minneapolis, March 7, on allergy. Dr. James S. McCartney, Jr., Minneapolis, gave demonstrations of pathology of the liver before the society, February 24, and Marjorie Taylor, director, Milwaukee Curative Workshop, spoke on "Place of the Curative Workshop in the Community." Dr. Leo M. Czaja, Chicago, addressed the society's meeting, February 17, on "Maggot Treatment of Osteomyelitis."

MISSISSIPPI

Bill Introduced.—H. 273 proposes to authorize the board of supervisors of any county to contract with a hospital for the medical and surgical treatment and hospitalization of the poor of the county, provided that not more than $2.50 a day for each patient may be so expended by the board.

NEW HAMPSHIRE

Personal.—Dr. Alphonse Wilfred Petit, Nashua, was the guest of honor at a dinner and reception given by citizens of Nashua, January 7, celebrating his completion of fifty years of medical practice in that city. Dr. Petit was graduated from Victoria University Medical Department, Montreal, in 1877, and came to Nashua in December, 1881.

NEW JERSEY

Tribute to Dr. Danzis.—The medical staff of Newark Beth Israel Hospital gave a dinner, February 11, in honor of Dr. Maximillian Danzis, chief of staff, marking his completion of thirty years' service to the institution. An oil painting of Dr. Danzis was presented to the hospital by Dr. Charles M. Robbins on behalf of the staff and accepted by Frank I. Liveright, president of the board of directors. Dr. Paul Keller, executive director of the hospital, presided; among the speakers were David I. Kelly of the Essex County Park Commission and Dr. Wells P. Eagleton. Dr. Danzis was born in Russia in 1874, and came to Newark in 1890.

Bills Introduced.—S. 98, to amend the workmen's compensation act, proposes to add pneumoconiosis to the list of compensable occupational diseases. S. 138, to amend the dental practice act, proposes that the certificate of the board of registration and examination in dentistry that the records of the board show or fail to show the issuance of a license to practice dentistry, or of an annual certificate of registration, shall be prima facie evidence of those facts in proceedings in which the board may be a party. S. 150 proposes to permit any trial judge, whenever in his opinion it may be necessary to settle the issues of any pending cause, to appoint, on his own motion, or on the motion of either party to the action, one or more disinterested expert witnesses. The appointment of such expert witnesses by the court is not to prevent either party from calling its own expert witnesses. A. 170, to amend the dental practice act, proposes (1) to add to the causes for which licenses may be revoked (*a*) conduct unbecoming dental practitioners, (*b*) violation of any rules or regulations promulgated by the board; (2) to permit notices of revocation proceedings to be served by registered mail; (3) to raise the annual registration fee required of dentists to $3, and (4) to prohibit the practice of dentistry by corporations. A. 172, to amend the pharmacy practice act, proposes to discontinue the licensing of assistant pharmacists. A. 174 proposes to authorize the board of medical examiners to create a division to be known as the "Division of Medicinal Liquor," and to promulgate such regulations as will allow licensed physicians to use their own judgment as to amount necessary in the prescribing of intoxicating liquor for medicinal purposes. A. 176 proposes that marriage licenses shall not be issued when either of the contracting parties at the time of making the application is infected with a venereal disease in a communicable stage; is an imbecile, epileptic or of unsound mind; or is or has been an inmate of an insane asylum, unless it appears that such person has been discharged as cured from the asylum. A. 224, to supplement the pharmacy practice act, proposes to limit the use of the terms "pharmacy," "drug store," "apothecary shop," etc., to places supervised by registered pharmacists. A. 253 proposes to establish a Department of Hospitals and Charities and to consolidate therein the Commission for the Amelioration of the Condition of the Blind, Board of Children's Guardians, Rehabilitation Clinics of the Department of Labor, Commission for the Rehabilitation of Physically Handicapped Persons and Boards of Managers of Institutions. A. 257 proposes to establish a Department of Health to succeed to and exercise all the rights and powers and to discharge all the duties now exercised and charged on the State Board of Health. A. 325, to amend the law regulating the practice of chiropody, proposes that the fitting, recommending or the sale of corrective shoes, arch supports or similar mechanical appliances by retail dealers shall not be deemed to be the practice of chiropody. A. 334, to amend the laws regulating the practice of chiropractic, proposes to authorize the board of medical examiners to permit any veteran of the World War, having the educational requirements specified by statute, to be licensed without examination to practice chiropractic.

NEW YORK

Personal.—Mr. Harvey J. Hill, White Plains, who originated the plan of the annual Red Cross roll-call, died suddenly, January 28, at the age of 51.——Dr. Charles C. Murphy, Amityville, president of the Suffolk County Medical Society, has accepted the chairmanship of the Suffolk County committee of the American Society for the Control of Cancer.

Society News.—Dr. Aaron S. Blumgarten, New York, spoke on "Practical Endocrinology," before the Nassau County Medical Society, Mineola, January 26.——Three papers on coronary diseases were presented before the Medical Society of the County of Albany, at Albany, January 20, by Drs. Charles A. Perry, James F. Rooney and Arthur W. Wright.——Dr. Joseph A. Johnston, Detroit, addressed the Saranac Lake Medical Society, February 3, on "Studies in Carbohydrate Metabolism."

Bills Introduced.—A. 895 proposes to permit a divorce, among other causes, where either spouse is insane or is physically incapacitated. A. 949 proposes to modify the limitations placed by law on the practice of physical therapy by technicians by allowing such technicians to use in the treatment of diseases, without the supervision of a licensed physician, actinotherapy, hydrotherapy, mechanotherapy, thermotherapy and electrotherapy, exclusive of the roentgen ray, and to diagnose and prescribe therefor. A. 1040 proposes to permit either spouse to institute proceedings to annul a marriage by reason of the lunacy of the other spouse.

New York City

Society News.—Dr. Samuel Weiss demonstrated a photographic gastroscope and showed a color film depicting the normal and abnormal states of the stomach before the New York Physicians Association, January 27.——Drs. Emil Koffler and Nathan B. Van Etten addressed the Bronx County Medical Society, February 17, on "State Health Insurance in European Countries" and "Recent Evolutions of Economics of Medical Service," respectively.——Dr. Salvatore di Palma gave a lecture under the auspices of the Medical Society of the County of Queens, February 5, on "New Treatment of Nonseptic Incomplete Abortions." Dr. Adolph G. De Sanctis gave a lecture on "Convulsions in Infancy and Early Childhood," February 19.——Drs. Thomas M. Rivers and Robert T. Frank addressed the Medical Society of the County of Kings, February 16, on "Nature of Viruses" and "Gynecological Conditions and Their Treatment in Children and Adolescents," respectively.——Drs. Martin E. Rehfuss, Philadelphia, and John B. D'Albora addressed the Medical Association of the Greater City of New York, February 15, on "Medical Treatment of Gallbladder Disease" and "Treatment of Ulcerative Colitis," respectively.

Friday Afternoon Lectures.—The Medical Society of the County of Kings has announced the program of its spring series of Friday afternoon lectures to be given at McNaughton Auditorium in Brooklyn. The speakers with their subjects are as follows:

Dr. Harrison S. Martland, Newark, N. J., "Pathology of the Heart," March 4.
Dr. Samuel A. Loewenberg, Philadelphia, "Differential Diagnosis of Acute Abdominal Conditions," March 11.
Dr. Theodor Blum, Manhattan, "More Common Diseases of the Teeth and Jaws," March 18.
Dr. I. Harris Levy, Syracuse, "Cancer of the Stomach," April 1.
Dr. Bernard Samuels, Manhattan, "Common External Diseases of the Eye and Their Treatment," April 8.
Dr. Dean Lewis, Baltimore, "Osteomyelitis," April 15.
Dr. Ernst P. Boas, "Treatment of Circulatory Failure," April 22.
Dr. Israel Strauss, "Neurological Diagnosis in General Medicine," May 6.
Dr. Louis E. Phaneuf, Boston, "Diagnosis and Management of Uterine Bleeding," May 13.

Medical Publications of Washington's Time.—As a contribution to the celebration of the two hundredth anniversary of the birth of George Washington, the Medical Society of the County of Kings has placed on exhibition in its library the writings of some of Washington's medical contemporaries. Best known among them are Benjamin Rush (1745-1813), a surgeon general of military hospitals during the Revolution and a signer of the Declaration of Independence; and Samuel Bard (1742-1821), first professor of the theory and practice of physic at King's College (now Columbia University), who was physician to Washington during his residence in New York as president. John Jones (1729-1791), a surgeon in the Revolutionary Army and first professor of surgery in King's College, was the author of the first medical book by an American writer, a treatise on the care of wounds and fractures, which is included in the exhibit. John Morgan (1735-1789), director general and physician-in-chief of the American Army, 1775-1777, who wrote the first brief for adequate medical education in the United States, and William Currie (1754-1828), an army surgeon who wrote some of the earliest works on epidemiology, are others whose writings are shown.

OHIO

Personal.—Dr. William H. Stroup, Spencer, recently retired as president of the town board of education after forty-two years of continuous service in that capacity.——Dr. John G. Anderson, Fayetteville, has been appointed health officer of Brown County to succeed Dr. William L. Faul, Russellville, who retired from active service.—Dr. William F. Moss, Maineville, was the guest of honor at a dinner, February 6, marking his fiftieth year in the practice of medicine.

Society News.—The Marion Academy of Medicine was addressed, February 3, among others, by Drs. John A. Dodd, Richard T. Morgan, Everett H. Morgan and Harold K. Mouser. The general topic for discussion was shock.——The Miami Valley Hospital, Dayton, has recently established a diabetic clinic, in charge of Drs. Benedict Olch and Thomas P. Sharkey.——Dr. Joseph H. Barach, Pittsburgh, addressed the Mahoning County Medical Society, Youngstown, February 16, on "High Arterial Pressure: Etiology, Classification and Treatment." Dr. John P. Tucker, Cleveland, will speak, March 15, on "Newer Viewpoints in the Treatment of Peptic Ulcer."——Dr. Frank W. Harrah, Columbus, addressed the Knox County Medical Society, Mount Vernon, January 28, on "Preoperative and Postoperative Care of the Prostatic Patient."——Dr. Mark H. Mothersill, Indianapolis, discussed "Recent History in the Treatment of Anemia" at a meeting of the Preble County Medical Society, February 18.——Drs. Harold A. Miller, Maurice E. Hodgdon and William Paul Dodds, of Pittsburgh, conducted a symposium on "Common Obstetrical Difficulties and Treatments" before the Belmont County Medical Society, February 4.

OKLAHOMA

Dr. Sigerist to Lecture.—Dr. Henry E. Sigerist, professor of the history of medicine and director of the Institute of the History of Medicine, University of Leipzig, Germany, will give two addresses in Oklahoma City, February 29, as the guest of the University of Oklahoma School of Medicine and the Oklahoma County Medical Society. His subjects will be "Medicine of the Renaissance" and "Medicine and Humanism."

PENNSYLVANIA

Eyesight Swindlers.—Two men calling themselves "Dr." Harris and "Dr." Sherman are reported to have swindled residents of Reading recently by pretending they were an ophthalmologist and a surgeon from the Wills Eye Hospital, Philadelphia, making examinations and performing so-called operations for cataracts. According to descriptions furnished by his victims, "Dr." Sherman wore a light checked suit and white gold glasses. He weighed about 150 pounds, was about 5 feet 6 inches tall, had a wart or pimple on his left cheek, and drove a light gray automobile with a New York license. "Dr." Harris was described as having a dark complexion, wearing a dark brown mixed suit, weighing about 180 pounds and about 5 feet 5 inches tall.

Society News.—Dr. Theodore O. Elterich, among others, addressed the Pittsburgh Academy of Medicine, February 9, on "Malignant Growths During Childhood."——At the meeting of the Allegheny County Medical Society, Pittsburgh, February 16, Dr. Roy R. Snowden spoke on "Nephrosis: Clinical Aspects and Mechanism of Edema"; Dr. James D. Heard, on "Removal of Foci of Infection: An Appreciation and a Protest," and Dr. John A. Hagemann, on "The Doctor Looks at His Critics."——A symposium on infant feeding was held at the meeting of the Pittsburgh Pediatric Society, February 19, at which the speakers were Drs. Ernest G. Kuhlman, George J. Feldstein and Carl L. Ruder.——Dr. William H. Mayer, Pittsburgh, addressed the Crawford County Medical Society, February 10, on "How the Medical Profession Has Served Humanity in Medical Emergencies."——Dr. Stanley L. Freeman, Wilkes-Barre, addressed the Luzerne County Medical Society, January 6, on appendicitis in infancy and childhood.

Philadelphia

Woman's College Forms Advisory Committee. — The Pennsylvania State Advisory Committee for the Woman's Medical College of Pennsylvania was organized at a luncheon at a meeting, February 13. The formation of this committee will be followed by the organization of similar committees in other states. Arising from these will be a national committee, to be chosen from the state committees, embodying the aspirations of those throughout the country who are interested in education of women in medicine. The Pennsylvania committee was formed to acquaint the people of the state with the immediate objectives of the college and its future ideals as well as of the progress it is making.

Posed as a Physician Seven Years.—Charles Borromeo Smith, who held himself out as a physician for seven years in various cities, was sentenced to three months' imprisonment and fined $100 and costs after pleading guilty, January 25, in the Chester County Court, to a charge of practicing medicine without a license. Smith, who is 31 years old, in 1925, is said to have impersonated a physician of the same name in Uniontown, having obtained a duplicate of the real Dr. Smith's diploma from the University of Maryland by writing authorities there that he had lost his certificate. In a statement to police he said that he had served as a store physician in Chicago, operated a sanatorium in Cleveland, and served as ship surgeon on a steamer plying between New York and the West Indies. He was for a time on the staff of the U. S. Marine Hospital at Ellis Island and even won a commission in the army reserve corps. His last "medical" work was at the Pennhurst state school for the feebleminded near Perkiomenville, Pa., where he had been for only two days when he was arrested.

SOUTH CAROLINA

Bill Introduced. — H. 1483 proposes to require that any poison offered for sale, resembling commonly used foodstuffs, shall be discolored so as to be readily distinguished from any food.

TENNESSEE

Health at Memphis.—Telegraphic reports to the U. S. Department of Commerce from eighty-three cities with a total population of 36 million, for the week ended February 13, indicate that the highest mortality rate (20.8) appeared for Memphis, and the rate for the group of cities as a whole, 11.9. The mortality rate for Memphis for the corresponding week last year was 9.5, and for the group of cities, 14. The annual rate for the eighty-three cities was 12 for the six weeks of 1932, as against a rate of 14.3 for the corresponding period of 1931. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have large Negro populations may tend to increase the death rate.

VIRGINIA

Bill Introduced.—H. TN. 420 proposes to accord liens to hospitals treating persons injured in accidents, on any judgments or settlements obtained by the injured persons by reason of their injuries. H. 186 proposes to create a Board of Barber Examiners and to regulate the practice of barbering.

WEST VIRGINIA

Dr. Crile Gives Lathem Lecture.—Dr. George W. Crile, Cleveland, delivered the second annual Lathem Memorial Lecture of the Medical Review Society of Huntington, January 21, on treatment of exophthalmic goiter. The Lathem Lecture was established in honor of the late Dr. Claude A. Lathem, who died in 1930. The Medical Review Society was formed in 1923 by a group of ten Huntington physicians for informal discussion of medicine and the allied arts and sciences. Members of the Tri-State Medical Society, in session at the time, attended Dr. Crile's lecture.

WISCONSIN

License Revoked.—At a meeting of the Wisconsin State Board of Medical Examiners, January 12, the license of Dr. Robert B. Smiley, Stevens Point, was revoked on a charge of manslaughter.

Evening Clinic for Working Women. — The Wisconsin Medical Women's Society opened a special clinic for working women who cannot afford private medical and dental care, February 8, at Mount Sinai Hospital, Milwaukee, according to newspaper reports. The clinic will be open on Monday evenings as long as there is a need for its service. The patients will receive all kinds of medical treatment except hospital care. The following women physicians of Milwaukee have volunteered their services: Drs. Eleanor Cushing-Lippitt, Elsa Ruth Berger Edelman, Frances Johnson and Gail F. Moxon, and Ruth M. Witcpalek, D.D.S.

County Society Sponsors Graduate Courses.—The educational committee of the Medical Society of Milwaukee County is sponsoring four courses of lectures in Milwaukee for physicians during the winter. A course on diseases of the nervous system and another on diseases of the heart have recently been completed. The third, on surgical diagnosis of the abdomen, began, February 1. The fourth course will be on diagnosis of the chest. These courses are conducted on a group unit plan. After the opening meeting the group splits up into small units, to each of which a local instructor is assigned. Each group then meets at least once a week for three sessions.

GENERAL

New Editor of Mental Hygiene. — Dr. Frankwood E. Williams, New York, editor of *Mental Hygiene* since its establishment in 1917, has retired from that position. He was succeeded by Dr. Clarence M. Hincks, director of the National Committee for Mental Hygiene. Dr. Williams retired from the directorship of the committee in November, 1930, after fourteen years' service (The Journal, Nov. 29, 1930, p. 1680).

Survey of Mental Disorders. — The National Research Council is sponsoring a survey of the present status of mental disorders in the United States, to be financed by a grant from the Carnegie Foundation. Madison Bentley, Ph.D., of the department of psychology at Cornell University, Ithaca, N. Y., has been granted leave of absence for part of the second semester of the present academic year, to conduct this study. As planned the study will attempt, first, to define the present state of the subject and to estimate the influence of each science now in the field, and, secondly, to discover what the underlying sciences have contributed to understanding and control of mental maladjustment and what the promise is for enlarging knowledge from these sources.

Fellowship Awarded by Foundation.—The Herbert Celler Foundation will award within the next few months a fellowship carrying an annuity of $750 for the year beginning July 1. Each candidate must submit with his application a personal record, a list of his publications, if any, an outline of the work he wishes to pursue and suitable recommendations. This information is to be sent to the secretary, Dr. Benjamin Eliasoph, 941 Park Avenue, New York. The Herbert Celler Foundation was organized to perpetuate the memory of Dr. Herbert L. Celler, who, until his death about four years ago, was associate attending physician at Mount Sinai Hospital. The money was obtained by voluntary contributions from lay and medical friends of Dr. Celler, the income from which was to be awarded to a suitable candidate to pursue further study or research either in the United States or abroad.

The income from the fund is usually about $1,000, but in view of the present financial situation, the annuity has been reduced for the time being.

News of Epidemics.—One hundred and twenty-five cases of smallpox were reported in the public schools of Arnolds Park, Iowa, February 4. The schools were closed in an effort to check the epidemic.——Public meetings were banned in a school district near Hamilton, Ohio, because of smallpox. Twenty-eight cases were reported under quarantine and fourteen patients had been released, January 30. Dr. Clifford J. Baldridge, county health commissioner, advised school authorities to order all students to be vaccinated or be excluded from school.——A recent outbreak of diphtheria at St. Joseph's Orphanage, Cincinnati, has been traced to a carrier among the children at the institution. Twelve children had had diphtheria since November.——An epidemic of influenza was reported, February 11, at the Ohio Soldiers' and Sailors' Orphans' Home at Xenia, where 170 of the 700 children were ill. Schools were closed because of influenza epidemics in Sibley, Iowa, and in Avon, Mount Carroll and Galva, Ill., February 4.——An outbreak of scarlet fever caused the closing of schools in Gnadenhutten, Ohio, February 5; 27 out of 400 pupils had the disease.

Bequests and Donations.—The following bequests and donations have recently been announced:

Church Charities Foundation, Brooklyn, $500,000 by the will of Mrs. Albertine C. Aikman for an addition to the foundation's hospital, to be known as the "Aikman Memorial" for incurable patients.

New York Polyclinic Hospital, $10,000 by the will of the late Elmer A. Darling.

Woman's Hospital, Manhattan, $10,000 by the will of the late Dr. J. Riddle Goffe, Bronxville.

Lutheran Hospital, Brooklyn, $2,500 by the will of the late Mrs. Anna Fulling, Tuckahoe.

Beth Israel Hospital, New York, $4,000 by the will of the late Archie M. Levy.

Chillicothe Hospital, Chillicothe, Ohio, $35,000 for a children's ward, by the will of Mrs. Elinor McKell Mayo, Los Angeles.

Wesley Hospital, Marshfield, Ore., $90,000 by the will of John Sherman Gray. The bequest will be deferred for a time but will ultimately be available after certain obligations involving the income have been fulfilled, it is reported.

Knickerbocker and Manhattan Eye and Ear hospitals, New York, $10,000 each under the will of the late Alfretta H. Gardner.

Presbyterian Hospital, New York, will ultimately receive $1,284,278 as the Wallace Fund, under the will of the late Mrs. Helen M. W. Swan.

The New York Academy of Medicine and the Manhattan Eye, Ear and Throat Hospital, $10,000 each under the will of the late James Brentano Clemens.

Presbyterian Hospital, Philadelphia, $20,000 by the will of Mary E. Joralemon, Ardmore, Pa.

Episcopal Hospital, Philadelphia, $5,000 by the will of the late Lillie M. Madeira.

Coatesville Hospital, Chester County Hospital and Homeopathic Hospital of Chester County, all in Pennsylvania, $2,500 each by the will of the late Frank Parke.

Medical Bills in Congress.—*Change of Status:* S. 894 has been favorably reported to the Senate, without amendment, directing the retirement of acting assistant surgeons of the United States navy at the age of 64 years (Senate Report No. 258). S. 1690 has passed the Senate, providing for the care and treatment of members of the National Guard, Organized Reserve Officers' Training Corps, and citizens in military training camps who are injured or contract disease while engaged in military training. S. 2978 has been favorably reported to the Senate, without amendment, providing for the construction and equipment of a hospital on the Blackfeet Indian Reservation in Montana (Senate Report No. 266). H. R. 7518 has been favorably reported to the House, with an amendment, authorizing the President to confer on the governor of the Panama Canal the right to issue and revoke licenses to practice the healing art under regulations to be issued by the governor and providing a penalty for violations of health regulations (House Report No. 530). *Bills Introduced:* Senator Copeland, New York, has submitted a proposed amendment to the appropriation bill for the Treasury and Post Office Departments, authorizing the importation of brandy and other spirituous liquors for medicinal and other nonbeverage purposes. The proposed amendment has the approval of the Treasury Department. S. 3678, by Senator Davis, Pennsylvania, to convert into a diagnostic center the veterans' hospital numbered 49, at Philadelphia. S. 3748, by Senator Connally, Texas, to amend an act entitled "An Act to recognize the high public service rendered by Major Walter Reed and those associated with him in the discovery of the cause and means of transmission of yellow fever," by including Roger P. Ames among those honored by the act. H. R. 9344, by Representative Patterson, Alabama, conferring on the Student Army Training Corps all the benefits of the World War Veterans' Act. H. R. 9488, by Representative Howard, Nebraska, "to reduce existing tariff duties upon table, household, kitchen, and hospital utensils, and hollow and flat ware."

Prenatal "Surgery"

Nature has been said to be a good physician but a bad surgeon. While recovery from disease depends on her efforts, nature fails in such surgical emergencies as gastro-intestinal perforations, severe hemorrhage or the displacements of fractures and dislocations. In a series of lectures on "Malformations of the Human Body Considered from a New Point of View," delivered at the Royal College of Surgeons, Sir Arthur Keith has shown that in embryonic development nature performs operations in many respects comparable with those of the surgeon, but surpassing in delicacy and perfection anything to which he can attain. The greatest of these developmental operations is the enclosure of the entire nervous system. The brain and spinal cord are only a transformed dorsal strip of skin of the embryo. It is remarkable that, although the brain is needed only after birth, it is the first of all bodily structures to be differentiated, appearing even before the heart has become functional and when the embryo is less than one twenty-fifth of an inch long. At this early period the skin of the back is being modified to form nerve plates. In the fourth week the margins of the nerve plates begin to rise, so that first a trough is formed and then a tube. The folded margins of the tube come into contact first in the neck. Edge becomes healed to edge, exactly as they do in a wound brought into apposition; only, the operation is more perfect, for no scar is left. From the neck the process of union spreads forward and backward; in less than a week it has reached the forehead and in less than two weeks the lower region of the trunk. In less than two weeks the whole central nervous system becomes submerged in an orderly manner and the line of submergence is obliterated by a covering of skin. If the operation fails completely, the child is born with the brain and cord exposed. More frequently the failure is partial and spina bifida results. It has been shown experimentally in the fish and the frog that spina bifida can be produced by subjecting the neural plates to injurious conditions—just as union is preventable in a wound.

The formation of the eye entails two operations of developmental surgery. Part of the embryonic tube grows out sideways as a pocket to form the retina. The closed end of this comes against the skin of the head, and the area touched begins to grow inward to form a pocket which abuts against the nerve pocket or outgrowth. Both pockets become shut off—the one from the embryonic skin to form the lens of the eye, the other from the neural tube to form the retina. So perfect is the healing at the point where the lens pocket becomes detached from the skin that no trace is left. Indeed, that part of the skin becomes the cornea. When the first stages of eye formation are completed, one side of the eyeball still remains open. This fissure is closed by a process similar to that which unites the two sides of a wound. If the closure is imperfect, coloboma results. The remarkable discovery has been made that the brain pocket, which grows out to form the retina, is a "master tissue." If it is prevented from coming into contact with the skin, no lens is formed, but if it is detached and embedded beneath any area of skin of the embryo, the overlying skin at once begins to form a pocket and lens. This almost magic power is due to a growth-controlling substance formed within the neural pocket. A similar influence is seen in the formation of galls on plants by insect larvae. Recently Professor Spemann of Freiburg discovered that a certain small area of tissue on the back of the embryo has even more wonderful morphogenic power. If a graft is taken from it and implanted in the side of the embryo, the surrounding tissue begins to form nerve plates and a new embryo. The key to some of nature's secret surgical processes, carried out in the routine building of the embryonic body, will be found in morphogenic substances. In the matter of repair, nature is still the master surgeon.

How have the elaborate operations described come into being? In the lowest invertebrates the nervous system is still essentially part of the skin. The elaborate growth and extension of the system in vertebrates became possible only when provision was made for the earlier stages of development being gone through in a position of shelter and nurture, as occurred in the elaboration of intra-uterine life.

Decline of Birth and Death Rates

The Health Section of the League of Nations has published a critical survey of the increase of population in the European countries, Australia, New Zealand and Japan, which constitute one third of the population of the globe. This shows a decline in both the birth and death rates. The fall in the birth rate has varied greatly in different countries. In Germany it is forty times that in Portugal and five times that in France. Japan is the only country in the group studied that has an increase of birth rate. France, which for a long time had the lowest birth rate, has now one higher than England, Austria, Sweden, Norway, Switzerland and Estonia. The decline in the death rate shows less variation. The greatest reductions are in Russia, Spain, Germany, Hungary and Estonia. England, Norway, Sweden, Denmark, Switzerland, Belgium and New Zealand show only a slight reduction to offset the sharp decline in their birth rates. This is because the death rate in these countries had already reached a low level. Since the beginning of the twentieth century the maximum decline in birth rate has been 47 per cent and in death rate 39 per cent, both figures being reached in Germany. Out of twenty-nine countries covered by the survey nine have had a decline of birth rate of more than one third and eight one of from 35 to 23 per cent. The average net increase of population in recent years shows no general diminution in comparison with the years 1900 and 1905. But there is for most countries some diminution. For England, Germany, Norway, Sweden and Belgium the natural increase in recent years is only one fourth of that of twenty-five years ago. For Austria, France and Switzerland there is a diminution of more than 50 per cent. On the other hand, Japan, Spain, Portugal, Ireland and Russia have had since 1928 a greater natural increase than at the beginning of the century. In the year 1928 Europe had an increase of 3 millions, without counting the soviet republics, which appear to have had an increase of more than 2,800,000. Poland, Germany and Italy had an annual natural increase of more than 400,000. Rumania, Spain and England come next with a natural increase of from 200,000 to 300,000. Among the extra-European countries the United States had an increase of 870,000 and Japan of 900,000. The continued fall in the birth and death rates has brought about important changes in the structure of population. The proportion of elderly people is greater and of younger smaller. These changes will in turn bring a rise in the general death rate and a further decline in the birth rate. In particular, the reduced generation born during the war will from 1935 to 1945 have an increasingly depressing effect on the birth rate.

The Danger of High Mountain Climbing

In regard to proposed high climbing in the Himalayas, Sir Leonard Hill, F.R.S., calls attention in the *Times* to careful research work carried out by Dr. Argyll Campbell while Sir Leonard was in charge of the department of applied physiology at the National Institute for Medical Research. Dr. Campbell kept more than 100 mammals of various kinds in an atmosphere equal to that at the top of Mount Everest. He found that not only did no acclimatization take place but there was progressive deterioration, which accompanied degenerative changes in the cells of the heart, liver and kidneys, the result of insufficient oxygen. Few of the animals survived for eight days, and the breathing of oxygen for short periods did not help. Dr. Campbell found that the degenerative changes began at what corresponded to altitudes above 20,000 feet. In this connection it is noteworthy that natives do not take their flocks above 18,000 feet. None of the famous climbers have spent more than ten days at great altitudes, such as 25,000 feet, and a significant lessening of efficiency has been reported: those who tried to reach the top of Everest lost their lives. Sir Leonard Hill points out that want of sufficient oxygen lessens the power of judgment. The power of any individual climber to resist this want cannot be tested by a short exposure to lessened atmospheric pressure. The advice of Sir Leonard is that climbers should aim at one or two of their party, who prove to be the most resistant, reaching the top as quickly as possible after leaving the base camp placed below 20,000 feet, before serious degeneration of the heart has taken place.

Decrease in the Incidence of Syphilis

The annual report of the British Social Hygiene Council (formerly the National Council for Combating Venereal Diseases) gives a survey of the venereal problem in this country since the inception of the government scheme fifteen years ago by which local authorities were required to provide the free diagnosis and treatment of venereal disease. The returns from the treatment centers, which deal with the great majority of cases, show that in the fifteen years new infections with syphilis have fallen by 50 per cent, a result attained by no other country except Sweden, where the teaching of social hygiene is compulsory. The evidence from the centers is supported by the statistics from the army and the air force. In the army the incidence of syphilis per 10,000 has fallen from 9.8 in 1921 to 2.1 in 1929 and in the air force from 4.1 to 0.8. In the army, regular instruction is given to all officers and men on the medical aspect of the problem. Further evidence of the decline of syphilis is the fall of the rate per thousand births of deaths of infants certified as due to syphilis from 1.34 in 1912 to 0.64 in 1929. Thus the bringing of the infected under treatment at the free centers provided by the state, as a means of preventing the spread of syphilis, has proved sound. But the council believes that a certain proportion of syphilitic women and children are escaping the operation of the scheme. The prevention of congenital syphilis by the detection and treatment of every case in prospective mothers appears to be well worth doing.

The efforts to cope with gonorrhea have been less successful. The number of cases treated at the centers shows a slight increase, but this is held to be due to a greater use of the centers rather than to an increase of infections. But the low ratio of cases of gonorrhea treated at the centers to cases of syphilis in women (1.18 to 1) suggests that a large proportion of infected women remain untreated. Far too many patients reach the centers after being months or even years under the care of physicians who have failed to recognize the disease. Among them are many suffering from arthritis, which should always stimulate an investigation into the question of gonorrhea. An important part of the reduction of syphilis is due to the action of arsphenamine in quickly making the patient noninfectious. It is said that the incidence of gonorrhea has not been affected because there is no such specific. But the council holds that if women came for immediate treatment more freely the incidence of gonorrhea would decline. It insists that public education is essential for the effective carrying out of the voluntary system of free treatment. This is proved by the fact that an increase of patients has followed lectures on venereal disease and the showing of films. The small proportion of women with gonorrhea who seek treatment shows the great need for educational measures with regard to this disease.

The Hematopoietic Potency of Carotene

Carotene has been the subject, in France, of important researches; among others, those of Maurice Javillier and of Mlle. Enrique, who have shown that carotene is capable of reestablishing the growth of rats subjected to a diet defective in vitamin A. Nevertheless, it is certain that carotene and vitamin A are different substances that present many distinctly different reactions. But the research of T. Moore and of S. Captain, on rats and pullets, has established that carotene ingested by these animals is transformed in their liver into vitamin A, of which a reserve supply is accumulated. Prof. Léon Binet and Mr. V. Strumza have recently discovered an interesting property of carotene that (although their experiments thus far have been exclusively on laboratory animals) appears to indicate that this substance performs an important rôle in therapeutics. It exerts a remarkable influence on hematopoiesis. Several lots of dogs were made anemic by venesection. In one lot, the restoration of the erythrocytes and of the hemoglobin was allowed to take place spontaneously, while, every day, the progress of the restoration was checked by an examination of the blood. In another lot, carotene was administered to the anemic animals, and it was found that in the latter the hemoglobin was restored more rapidly to normal than in the controls. At the same time the number of erythrocytes increased in the same proportion. To be sure, these experiments had to do with only one form of anemia, and it remains to be determined in man what the effects of this treatment would be in pernicious anemia and in anemia due to hypochlorhydria. One must not, however, overlook the fact that in animals the reserve depot of vitamin A is found in the liver. Mouriquand has already demonstrated that a deficiency of vitamin A accompanies a marked anemia. The question may therefore be raised, though possibly hazardous, as to whether the secret of the effects of the ingestion of calf's liver in anemia does not lie in the fact that the liver is the depository for vitamin A.

Measurement of Quantity of Radium Rays Employed in Treatment

A valuable device invented by Dr. Lucien Mallet has been introduced for the measurement of the quantity of gamma rays of radium used in a radium therapeutic treatment and presented to the Academy of Sciences. It consists of two independent parts: a small ionization chamber, which is introduced into the cavity or the tissues to be treated, and an electrometer capable of measuring the minutest electrotonic charges. After the operation, the ionization chamber is attached to the electrometer, which indicates accurately the loss of load represented by the quantity of gamma rays dispensed.

Medicolegal Value of Dust Found in Watches

Dr. Severin Sicard of Marseilles, to whom medicine is already indebted for the discovery of a sure test of death (the injection of a solution of fluorescein), has just published an article on the medicolegal value of the microscopic examination of the dust found within watch cases. Watch cases always contain more or less dust, which finds entrance through the various openings in the case—through the spaces about the hinges, through the opening for the winding stem, and around the margin of the watch crystal. Dust penetrates by aspiration when the watch, carried at body temperature in the vest pocket, has first driven out a part of the air that it contains and that the heat has expanded and then, having returned to a normal temperature, draws in the air and the dust that it contains. Mr. Sicard confirmed these statements by a few simple experiments. He covered a watch with flour and placed it near a heated surface. Later he inspected the watch and found no trace of flour within it; but, on performing the experiment a little differently, and, before opening the watch, leaving it for a time exposed to the outside temperature, he always found flour within it. An examination of the dust found in watches may supply useful information as to the trade or profession and the usual occupations of the subject when there are found certain substances in quantities exceeding by far those found in ordinary dust, or when the substances are absolutely characteristic in themselves. Flour is found in the watches of bakers, coal dust in the watches of miners and of stokers, baked clay in the watches of brickmakers, iron and copper on metal workers, bits of vegetable peelings on workmen handling such products in a dry state, particles of hair on hair-dressers, fragments of raw wool on wool washers, and plaster and cement on masons. The same substances, if a careful search is made, will be found in the handles of pocket-knives and in the tubes of small keys. Watches worn on the wrist by women or kept in their handbags contain rice powder, and one finds resin dust in the watches of violinists. Such information may be of great aid to the police in their researches. A watch found on a person accused of having stolen it was certainly stolen if it is found to contain flour or coal dust, whereas the accused person has never been either a baker or a coal miner. Dr. Severin Sicard had already previously made similar observations in studying microscopically the dust that becomes mixed with the ear wax in the exterior auditory meatus.

Possible Injury to Germ Cells by Roentgen Rays

A recent letter touched on the question of possible injury to germ cells by roentgen rays (The Journal, Nov. 21, 1931, p. 1552). On account of its great importance, this problem has occupied of late, in Germany, many persons engaged in that line of work. For that reason, the Berlin Gesellschaft für Geburtshilfe und Gynäkologie devoted recently a session to a discussion on temporary "castration" by roentgen rays, which was participated in by many prominent gynecologists, researchers on heredity and radiologic experts. The opening paper was presented by Privatdozent von Schubert, on the staff of the Frauenklinik der Charité, who called attention to the difficulties of the method. Temporary castration is unsuccessful in 5 per cent of the cases; on the other hand, supposedly temporary castration will, in a like percentage of cases, prove permanent, which is a serious matter for young women and may give rise to criminal or civil suits. The uncertainty of the method is due chiefly to the two facts that one does not know exactly what roentgen dosage it is necessary to employ and that women of a given age do not all react in the same manner to a given dosage. Furthermore, there are other modes of treatment, so that in the Frauenklinik der Charité this method is not employed.

The physical and technical problems were discussed by the Berlin radiologist Professor Friedrich and the Erlangen gynecologist Professor Wintz, who contends that the strength of the roentgen dosage can be determined within 5 to 10 per cent. Professor Martius of Göttingen and Prof. Eugen Fischer of Berlin-Dahlem discussed the questions pertaining to possible injury of the germ cells by irradiation of the ovaries. That the modifications in the germ cells brought about by roentgen rays may give rise to mutation has been shown by the experiments on flies (Drosophila). Conclusions with regard to man must of course be drawn with great caution; but it is certain that we do not know as yet what dosage applied to man may be considered harmless. While it is true that the conditions in the ovary of Drosophila are different from those obtaining in man, and also that mature ova are more sensitive to roentgen rays than immature ova, even the latter may be killed and a permanent castration be brought about. Professor Nürnberger, gynecologist in Halle, does not regard the danger as very great, and emphasized that no evidence is available to show that roentgen mutations occur in man as the result of roentgen irradiations. It is clear from this discussion that, in any event, there is no assurance that an injury of the germ cell by roentgen rays may not occur, and the indications for the application of this method must hence be drawn with great reserve.

New University Clinics in Freiburg

In spite of the economic depression, an endeavor is being made to complete buildings that have been begun, if the money for them has been appropriated and is available. What retrenchments have become necessary in the field of science was explained in previous letters. A short time ago, the newly erected medical and surgical clinics of the University of Freiburg, Baden, were dedicated. Their construction and hygienic arrangements are of the most modern type, so that it is doubtful whether they are excelled by any similar institutions in Germany or elsewhere. The two new university clinics have about 700 sick-beds. It is planned to erect later in a similar style a new ear, nose and throat clinic, which will complete the so-called Klinikenring. The funds for the two buildings erected (about $4,000,000) were furnished in part (two fifths) by the city of Freiburg and in part by the government of Baden (three fifths). It is estimated that the buildings to be erected will require the expenditure of nearly $2,000,000 more.

The Three Hundred and Fiftieth Anniversary of the University of Würzburg

On Jan. 2, 1932, the University of Würzburg celebrated its three hundred and fiftieth anniversary. The university was established in 1402 but was closed in 1413 and was not reopened until Jan. 2, 1582. In contrast with most other schools of higher learning that were the outgrowth of the Reformation, this university was designed by the bishop-prince as a stronghold of catholicism. The university retained its ecclesiastical character until the end of the eighteenth century. When, however, in 1803, it came under the control of Bavaria, it took on a more liberal character. Of the more eminent members of the faculty of medicine in modern times may be mentioned Virchow, Rokitansky and Roentgen. The faculty of medicine achieved, however, a period of greatness about fifty years ago, when Kolliker, C. Gerhardt, E. von Bergmann, Szanzoni and Michel formed a brilliant galaxy. A portion of the university is still housed in the old building that dates back to 1582-1591, a beautiful Renaissance structure with a church whose magnificent tower serves as an observatory. For the clinics, new buildings have been erected in comparatively recent times; but the old Julius Hospital, well known to many German and foreign students since their university days, is still in use.

Research on Vitamin B

The year 1931 stands out above all others in the history of biochemical research. In the course of a few months, in one of the most difficult fields, the chemistry of vitamins, remarkable advances were made. Three important vitamins have been obtained in a crystallized and absolutely pure state, vitamin A having been secured by Professors Euler and Karrer; vitamin C by the young Norwegian Rygh, and vitamin D by Prof. Adolf Windaus of Göttingen, working in collaboration with his pupils. Following these discoveries, the latest event is the exhibition, in a pure state, of that portion of vitamin B that is known as B_1, the factor that is effective against beriberi.

Intensive research has been made on this vitamin since 1926, when Jansen and Donath in the Netherlands succeeded in isolating from rice bran a crystallized substance active against a beriberi-like disease of pigeons. The Netherlanders regarded the substance as a nitrogen-containing base—apparently an alkoloid. Several attempts at verification yielded fluctuating results with reference to the activity of the crystals, which awakened some doubt as to their purity. Further doubt was injected into the matter by the fact that these crystals could not be isolated from yeast, known to be rich in vitamin B. The Göttingen chemist Prof. Adolf Windaus, and Prof. Fritz Laquer of the I. G. Farbenindustrie, in collaboration with other scientists, have improved so markedly the method of Jansen and Donath that they have now obtained from yeast a preparation of the vitamin that can be regarded as uniform and pure. Jansen's assumption that the newly discovered substance is a nitrogen base was confirmed. It contains, however—strange to say—also sulphur. Its potency is about three times greater than that of the best preparation heretofore known. In experiments on pigeons it was found that about 0.0024 mg. suffices for the prevention of the severe convulsions that are due to the lack of vitamin B_1.

Jan. 8, 1932.

Regulations Concerning Use of the Term "Specialist"

During the deliberations of the Vienna chamber of physicians, last year, Dr. Sonnenfeld presented a communication in which he explained the present regulations concerning the assumption by physicians in Austria of the title of "specialist." At present there are no legal regulations bearing on the right to assume and use the title of specialist in the republic of Austria. Only with regard to the admission of physicians to the *krankenkassen* having free choice of physician has any regulation of the specialist problem been attempted. As affecting the contracts between the organization of the medical profession and the *krankenkassen*, the following regulation obtains: "Only such physicians who, following a special course of training, confine their practice to a special branch of medicine are entitled, in principle, to announce themselves as specialists. Such physicians are recognized by the economic organization of physicians as specialists and are announced to the *krankenkassen* expressly as specialists for a certain branch of medicine. They are not permitted to serve, at the same time, as general practitioners." Every specialist must be a member of the Verband der Fachärzte (league of specialists) in Vienna if he wishes to practice in Vienna. In the provinces outside Vienna the title "specialist" is approved, by the chamber of physicians having jurisdiction, only after the applicant has furnished evidence of his special training. The special training required has been standardized by the Verband der Fachärzte in the following manner: A specialist can practice in only one of the following fields: surgery, dermatology, gynecology (including obstetrics), internal medicine, respiratory organs, neurology and psychiatry, ophthalmology, orthopedics, otorhinolaryngology, pediatrics, physical therapy, roentgenology, urology and medical laboratories, or a total of fourteen specialties. That holds for Vienna; in the provinces the three specialties orthopedics, urology and medical laboratories drop out. In case of need, the chamber of physicians has the right to combine two or more specialties (internal medicine and pediatrics, and respiratory organs, or ophthalmology and otorhinolaryngology, or surgery with gynecology and radiology). Every specialist in Vienna or in the provinces must first request admission to the narrower group and furnish proof that he has fulfilled the conditions for admission as specialist, which, for the nonoperative branches, are at least four years of training in a clinic or hospital service dealing with his specialty, and, for the operative specialties, five years of training and experience in such an institution. The applicant must also furnish proof that, for at least two years of the four to five year period, he served as assistant to the department head and was thus compelled to work more or less independently. The applicant is not recognized by the Verband der Fachärzte until the group of specialists concerned has admitted him; he can then enter into contracts with the health insurance societies (*krankenkassen*). But in case a physician does not seek service with the *krankenkassen*, he can select any specialty he desires, specialize in that branch of medicine, and announce himself as a specialist in that branch; and, if he desires, he can practice also general medicine, which the members of the specialist groups are strictly prohibited from doing, as has already been mentioned. But he cannot be admitted to membership in the Verband der Fachärzte. It should be noted, however, that the general public has become so used to regard and patronize only the members of the Verband der Fachärzte as specialists that the other specialists receive little consideration. The only specialist title that is protected by law in Austria is that of *zahnarzt* (physician-dentist), since the study of dentistry is regulated by law and only doctors of general medicine who devote themselves exclusively to dentistry may call themselves *zahnarzt*, other persons ("dentisten," technicians, and others) not being permitted to refer to themselves as *zahnärzte*. In Vienna there are something over 4,000 registered physicians, for a population of 1,810,000. Of that number, 800 are hospital physicians, 1,220 specialists, 650 physician-dentists (*zahnärzte*), and the remainder (about 1,400) general practitioners, 290 of whom are women. Among the specialists and physician-dentists there are 110 women. In Austria, outside Vienna, there are about 2,600 registered physicians, with about 600 specialists and physician-dentists.

Poisoning from Illuminating Gas

The use of gas for the lighting of streets in the larger towns of Europe goes back about 100 years, having been employed in Vienna for the first time in 1827. It is only during the past fifty years that public buildings and apartments have used gas, to any great extent, for illuminating purposes. With the beginning of this century gas began to be widely used for heating and cooking purposes, and now it is used quite generally even in small households. As a result, the opportunities for poisoning have increased. In 1914 there were 152 such cases of poisoning in Vienna, with 12 deaths; in 1930 the number of cases of poisoning rose to 1,360, with 446 deaths. A frequent cause of such accidents is the lack of knowledge of the use of gas-burning apparatus. In recent years, more than 40 per cent of all attempted and successful suicides in Vienna were accomplished with illuminating gas. The poisonous effect of the gas is due chiefly to the carbon monoxide it contains, the percentage of which varies considerably, dependent on the raw material used and the mode of production. The Austrian gas works produce illuminating gas with from 18 to 37 per cent of carbon monoxide; in Vienna the gas contains 16 per cent of carbon monoxide. There are no statistics of poisoning due to illuminating gas in Austria in earlier decades, so that it must have been a rare occurrence. About five years ago Dr. Damianos, who publishes this report in the *Mitteilungen des Oesterreichischen Volksgesundheitsamtes*, collected the first accurate data, with the collaboration of the police department in Vienna and the municipal gas works. It is interesting to note that in 1883 on three occasions municipal aid was given in connection with fatal gas poisoning. In 1892 there were 8 deaths and 18 first-aid treatments, whereas in 1930 in Vienna there were 380 suicides, 66 fatal accidents and 914 nonfatal accidents and attempts at suicide—an enormous increase in forty-seven years. The statistics collected by Dr. Damianos present the following picture: Cases of poisoning by illuminating gas increased slowly from 1883 to 1907; then from 1908 to 1914 there was a more rapid increase, and after the war the figures jumped up rapidly: 1890, 11 cases; 1900, 53; 1910, 149; and in 1928, 430 fatal and 1,013 nonfatal cases. Since 1928 the figures have not changed much. Furthermore, the statistics show that the number of suicides with gas exceeded by far the number of accidents (if one considers records of the last few years): 397-33, 398-77 and 380-66. It will be seen that about 40 per cent of all cases of poisoning with gas are immediately fatal and of the nonfatal cases more than 60 per cent were severe cases necessitating hospitalization of the patients. From 1890 to 1899, only 1 per cent of all suicides in Vienna were accomplished by means of gas; in 1928, however, the percentage was 40; in 1929, 41; in 1930, 45. If one compares the number of suicides and accidents by gas in Vienna with the number so occurring in the remainder of Austria, one gets the following figures: In 1913 there were 211,825 gas consumers in Vienna as against 35,975 in Austria; in 1928, however, the ratio was 463,220 to 69,775; in 1929 it was 468,033 to 72,398. In 1928 there were 397 suicides in Vienna and 15 in Austria, and a total of 1,443 gas accidents in Vienna as against 50 in the remainder of Austria. In 1929 there were 398 suicides in Vienna and 29 in the provinces, a total of 1,441 gas accidents as against 84 in the rest of Austria. It appears that the number of gas accidents has now been stabilized and that before long one may count on a decline.

Death of Prof. Benjamin Lipschütz

The death of Prof. Benjamin Lipschütz, the well known investigator and dermatologist, at the age of 53, has been announced. Professor Lipschütz devoted his attention chiefly to the biologic problems of dermatology and venerology. Various types of disease that he studied in detail and described bear his name; for example, ulcus vulvae acutum Lipschütz, erythema migrans Lipschütz, epithelioma contagiosum. His most important field, however, comprised the so-called inclusion diseases. In his "Manual of the Protozoa," he described the Chlamydozoa theory, molluscum contagiosum, fowl plague and the strongyloplasmata. Furthermore, he studied and published important articles on the cell structure of malignant growths. In 1915 he was made privatdozent, and, only a short time before his early death, he received the title of university professor, an honor that he, in his modesty, had never hoped to attain.

Labor Contract Affecting the Natives of the Congo

A new order has gone into effect in the Belgian Congo region, some features of which, pertaining to the hygiene of labor, deserve to be noted. The care of the health of workmen, porters and paddlers, employed in the commercial, industrial and agricultural enterprises, is placed under the control of a government physician, designated by the governor of the province as inspector of health of workmen, and of accepted physicians commissioned by him as assistant inspectors with only local authority. The inspection of the health of workmen has the special mission of supervising the regulations pertaining to the health of employees and of prescribing such measures as are needed to safeguard the lives and health of workmen employed in enterprises that are of a markedly dangerous and unhealthful character. It functions in collaboration with the inspection service of industry and commerce, communicates to the latter the sanitary measures that it prescribes, and gives it all the necessary technical instruction. If the measures prescribed by the inspection of health appear to the employer to be ineffective or burdensome, he may appeal to the governor of the province, whose decision, and the basis therefor, are forwarded to the complainant and to the author of the measure that was the object of the inquiry. No one may recruit or employ a native who has not been shown to be physically adapted to the work in question, nor may employees be required to do work for which they have not been shown to be fitted. The examination as to physical aptitude for a given type of work is made by a government physician or an approved physician.

Every employer and labor agent must provide gratuitously whatever medical care is needed by employees and recruits, and, in order properly to meet this obligation: 1. The employer must, irrespective of the number of employees, place at the disposal of the head of the camp a first-aid kit containing the drugs and dressings in current use, in a perfect state of preservation, ready for immediate use and amply sufficient for the purpose intended, and he must have a portable medicine chest if he employs porters or paddlers. 2. When the number of workmen exceeds 100 men, employed in the same place or distributed within a radius of 15 kilometers, he must employ a native man nurse, and additional men nurses at the rate of one nurse for each 200 employees; he must employ a white nurse if the number of workmen reaches 500 men, or one white nurse for each five native nurses employed if the workmen are scattered; he must entrust the medical service to a physician if the number of workmen reaches 1,000. 3. In every camp or settlement comprising more than 100 workmen, he must provide a special building to be used as an infirmary or hospital, if there is no hospital within a radius of 25 kilometers of the enterprise; the infirmary must have a number of beds equal to 5 per cent of the number of workmen, and there must be medical assistants provided, who, if they are not under the direction of a graduate physician, are placed in charge of government physicians. 4. The infirmary or hospital must keep a daily record of the number of patients, the nature of the disease, the date of its onset and the date of the recovery, and if more than 100 workmen are employed, an abstract of the record must be sent each month to the medical inspector of health.

Belgian Society for the Prevention of Blindness

The first session of the Association belge de prophylaxie de la cécité, the object of which is to combat the various causes of blindness, was held recently. The program outlined by the new society is identical with that of the Association internationale de prophylaxie de la cécité, an organization, with headquarters in Paris, which centralizes the efforts of the various chapters that exist in nearly all parts of the country and that has attained considerable development in foreign countries, notably the United States and England. The new society plans to work in collaboration with the existing societies that deal with the care of the eyes as a secondary feature of their program (Croix-Rouge de Belgique, Croix-Rouge du Congo, Ligue contre le péril vénérien, Ligue contre la tuberculose, Oeuvre nationale de l'enfance, Ligue d'hygiène mentale, Ecole centrale du service social). It will give its whole attention to the crusade against occupational eye accidents and will keep in touch not only with government but also with private industrial undertakings, and with organizations engaged in the prevention of occupational accidents. Finally, it will act on its own account by the diffusion of tracts and advice on health matters and by the organization of lectures. Professor Van Duyse, member of the Academy of Medicine and professor of the University of Ghent, is the organizer of this new society, which numbers among the members of its organizing committee many high officials and many leading ophthalmologists.

Reorganization of Institutes of Physical Education

Experience has shown the necessity of modifying the work and studies of the higher institutes of physical education. Likewise, a higher institute of physical education has been organized as a department of the faculty of medicine at each of the two government universities, located at Ghent and at Liége, respectively. The institute confers the degrees of licentiate of physical education, agrégé of physical education, and doctor of physical education.

Life Insurance for the Medical Profession

At the congress of the Fédération médicale belge, Dr. Peeters took up the subject of life insurance and pensions for the medical profession. Three matters were brought to the attention of his hearers: (1) the significance of life insurance in general, (2) mutual life insurance as a system, and (3) the appointment of a managing directorship. As regards mutual life insurance, experience has shown the incompetence of medical men in financial matters, for which reason mutual life insurance is contraindicated for physicians. There is a natural incompatibility between "business management" and the "medical temperament." The appointment of a managing directorship consists in entrusting to a competent and responsible organization what, owing to medical incompetence and incompatibility, medical men have never been able to compass. A managing body composed of members of the medical profession should be replaced by a managing directorship that has proved its ability in matters of life insurance. Following the presentation of this report, the congress decided (1) to appoint a committee that would unite, under the egis of the Fédération médicale belge, all the scattered mutual aid societies, in order that they may attain a maximum of efficiency, and (2) to get in touch as soon as possible with a life insurance company, or with a firm of actuaries, or with whatever organization appears proper for the realization of the purpose, with a view to organizing an insurance and pension system for physicians.

ITALY

Dec. 31, 1931.

National Congress of Surgery

The Società italiana di chirurgia held its thirty-eighth national congress in Bari, under the chairmanship of Professor Righetti. The official speakers on the topic "Associated Syndromes of the Right Half of the Abdomen" were Prof. Nicola Leotta of Bari and Dr. Giulio Vita of Palermo. Leotta divided the associated syndromes of the right half of the abdomen into four groups: (1) right abdominal syndrome; (2) right abdominal syndrome with cholecystitis; (3) right abdominal syndrome with gastric ulcer; (4) right abdominal syndrome with cholecystitis and gastric or duodenal ulcer. The right abdominal syndrome comprises changes in the appendix, and the adjacent intestine and lesions of the omentum and the perivisceral structures. One must assume the constant existence of an appendicitis, active or inactive. The foregoing changes are the result of a chronic peritoneal infective process.

The peritoneal lesions are associated with a simple chronic peritonitis of digestive origin, in which appendicitis plays a big part. The complex symptomatology results from three principal factors; namely, the peritoneal inflammatory factor, the mechanical factor (retraction of the meso-appendix, adhesions) and the nervous factor. There are digestive disturbances, spontaneous pains, chronic intoxication, and symptoms due to the lesions of the internal organs. The right abdominal syndrome with cholecystitis differs from the preceding owing to the coexistence of cholecystitis. This is manifested by classic biliary colic or by less intense attacks of pain. The right abdominal syndrome with ulcer is associated with the presence of a gastric or duodenal ulcer. These are of infectious origin, due to ascending infection.

Dr. Giulio Vita, who discussed the radiologic part of the topic, described the technic employed in the study of the associated syndromes of the right half of the abdomen. In the stomach are observed changes in form due to retraction of the lesser omentum, often accompanied by atonia and constipation.

The antrum of the pylorus may undergo traction, from which marked shifting to the right results. The duodenum may present retropositions of the bulb, deformations of the first and second portions, and/or spasmodic or paretic conditions of the ampulla of Vater. For the diagnosis of adhesions of the colon the speaker suggests the adoption of his method of studying the behavior and the changes of form that the colon undergoes before and after the ingestion of a drastic purgative.

Pozzi of Milan spoke on the syndrome of chronic appendicitis in tuberculous mesenteric glands. Surgical intervention in these cases alone will clarify the diagnosis and appendicectomy will prevent secondary infections of the glands.

Dr. Guido pointed out the value of the Meltzer-Lyon test in the associated syndromes of the right half of the abdomen; it represents a valuable aid in the diagnosis of lesions of the biliary passages.

ACUTE AND CHRONIC PANCREATITIS

The second topic, "Acute and Chronic Pancreatitis," was treated in collaboration with the Società di medicina interna. Prof. Antonio Gasbarrini of Bologna pointed out that the inflammatory processes that affect the pancreas cause reactions not only in the parenchymal tissue but also in the supporting tissue; to these may be added, as characteristic factors, cellular necrosis, hemorrhages and steatonecrosis. The general clinical symptoms of these lesions furnish few factors that aid directly in the diagnosis. Diagnostic importance attaches, however, to the pain, the discovery of tumors at the site of the pancreas, and functional disorders. The digestive tests, particularly the amount of fecal fats, according to Zoia, acquire importance for the diagnosis of chronic pancreatitis, while in the acute (necrotic) forms an increase in the diastase content of the blood and the urine appears to be especially significant.

The study of the lipase in the blood serum does not furnish a secure basis of judgment, and the same is true, as regards chronic pancreatitis, of the amount of fecal ferments, of which only trypsin apparently furnishes presumptive criteria worthy of consideration. Acute pancreatitis includes a necrotic form, a suppurative form and a gangrenous form. The primary factor in the characteristic succession of pathologic symptoms appears to lie in the cellular necrosis, which results in the liberation of a ferment that is a potent stimulus to the production of trypsinogen. The edema, the hemorrhages, the peritoneal reactions, and the fatal toxic factors are secondary to the local and general action of the trypsin. Chronic pancreatitis, more frequently than acute, accompanies diseases of the surrounding organs, especially disorders of the biliary passages and of the duodenum. The characteristic lesions consist chiefly of hyperplasia and sclerosis of the supporting tissues, and atrophy of the glandular parenchyma. The insular tissue is often spared but is sometimes hypertrophic. The clinical symptoms consist in phenomena of compression of such nearby organs as the common bile duct and the duodenum, and, often, in the presence of a palpable tumor. There is sometimes little pain. The prognosis is in direct relation to the possibility of direct surgical intervention for the removal of the original focus of infection.

The surgical part of the topic was presented by Professor Tusini of the University of Genoa. The etiologic factors of acute necrosis of the pancreas, he stated, are all capable of producing within the gland activations of the pancreatic ferment. The disease begins suddenly with grave shock, acute epigastric pain (especially on the left side), and persistent vomiting of bile. The temperature is normal or nearly so; there are intense cyanosis and dyspnea without demonstrable pulmonary and cardiac changes. There is evident relationship between the state of collapse and the nature of the pulse. Operative intervention is indicated, but it is necessary to select the opportune moment (more or less early). Chronic pancreatitis is rather frequent, especially with biliary complications. The symptomatology furnishes no pathognomonic signs, and hence the clinical diagnosis is extremely difficult. It is important to proceed systematically with an accurate exploration of the pancreas, and it may be desirable to resort to biopsy. The treatment varies. If there is icterus, treatment consists in biliary drainage, which relieves the retention of the bile and often cures, of itself, the pancreatitis. Biliary drainage may be applied either by drawing off the bile or by diverting it within by means of various anastomosis procedures, according to the needs. Cholecystostomy often heals, with a minimum risk, the inflammatory lesions of the pancreas, making it possible to survey the evolution of rebellious forms and to apply, in the second stage, if necessary, an appropriate treatment. Depending on associated lesions caused directly by the pancreatitis in adjacent organs, corresponding operations may be introduced, for the most part on the stomach and on the duodenum.

Dr. Calzavara of Treviso emphasized the significance of acute hyperglycemia for the early diagnosis of acute necrosis of the pancreas. He said that researches on hyperglycemia should be made systematically in cases of acute abdominal lesions in which pancreatitis is suspected.

Drs. Biolato and Villata of Turin discussed the behavior of Bacterium coli cultivated from the pancreas, in relation to experimental pancreatitis. The researches of these authors have shown that the pancreas has extraordinary resistance to infection, which may be brought about through the blood stream or by the canalicular route.

Dr. Zaffagnini of Parma experimentally produced acute pancreatitis by the introduction of foreign bodies into Wirsung's canal. On introducing the foreign body externally into the intestinal lumen, he observed the genesis of a simple chronic pancreatitis, such as can be brought about by the simple ligation of the canal. When, however, the foreign body was introduced by the duodenal route, after a moderate edema and intralobular and perilobular infiltration there was restitutio ad integrum.

Before adjourning, the congress selected Rome as the next meeting place.

TURKEY

(From Our Regular Correspondent)

Ankara, Jan. 25, 1932.

Repeal of Compulsory Governmental Service for Physicians

In view of the scarcity of physicians in the remote eastern provinces, a law was passed in 1923 according to which a two years' compulsory governmental service was required of the graduates of the medical school. Women physicians were exempt, chiefly because of unsatisfactory living conditions and other professional hardships in the remote provinces. The enforcement of this law has almost accomplished its purpose but seems also to have resulted in fewer applications for admittance to the medical school by candidates who pay their own expenses. So, partly owing to the fact that the majority of vacancies in the eastern provinces are filled now, a bill has recently been introduced into the national assembly according to which this law will be repealed. Only physicians graduating hereafter will benefit by this repeal; those at present working on their two years' term will be required to terminate it. But physicians who have studied at government expense and who have lived all or part of the required time at the government's medical students' home will continue to serve their term in governmental service. The license of a physician found guilty of shunning his obligations in this respect will be withheld for five years, and he will be required to bear the whole cost of his education. Students who have studied at government expense and lived at the medical students' home and who give up the study of medicine, or who for reasons other than physical unfitness have been advised to leave the medical school or home for good, will also be required to pay their expenses.

Alcoholic Beverages Invade the Rural Communities

Alcoholic beverages are forbidden all true believers of Islam, and until recently alcoholism has not been a problem in Turkey. The establishment of ale houses or bars within a Mohammedan community, or in the vicinity of a mosque, was prohibited. Wine was used on the occasion of the celebration of a wedding or of a circumcision, but without such an excuse it was used by a Mohammedan only clandestinely in the home, for if it became known, all household members would be ostracized. Three decades ago uniformed officers were rarely seen using alcoholic beverages openly; they were not permitted to enter places where these were served. But customs have changed with regard to their use, especially since the World War, and now in the large cities alcoholic beverages have entered almost every home. During the war of independence, prohibition was enforced throughout Anatolia; but prohibition was abandoned four years later, partly because of the difficulties in enforcing the law and partly because a monopoly constitutes a source of income; so a government monopoly was instituted instead. Though the monopoly made alcoholic beverages more expensive, they are now in demand even in remote provinces and, according to press reports, the first train bound for Malatia on the opening of the new railroad line to Malatia in 1931 carried ten carloads of them. At the last national medical congress Dr. Fahreddin Kerim, associate professor of mental diseases at the medical school and secretary of the Green Crescent, the Turkish antialcoholic society, reported that alcoholic beverages had lately found their way into the rural communities. When crops fail and peasants work in town they become acquainted with alcoholic beverages and introduce them in the villages. The alcoholic drink generally preferred in Turkey is "raki," which is made from fresh grapes. It is white and distilled, and is flavored with anise; its alcohol content varies from 40 to 60 per cent. The second most popular drink is beer. Turkish women formerly never touched anything containing even the slightest trace of alcohol, but since their emancipation after the World War they have given up their repugnance and today the society woman does not despise a glass of wine at a party. It is mostly during the summer that youths get acquainted with alcoholic beverages by taking a glass of beer in a beer garden. In view of the ever increasing automobile accidents due to intoxicated drivers, and the increase in homicides and divorce traceable to the use of alcoholic beverages, the antialcoholic society has proposed a law to close saloons, thus confining the use of alcoholic beverages to the home.

The Prevention of Cerebrospinal Meningitis

Cerebrospinal meningitis is rare in Turkey, but in the winter of 1928-1929 it was epidemic in Tarsus, near Adana. The disease seemed to have disappeared but during the autumn of 1930 it reappeared in the same locality and during the winter of 1930-1931 an epidemic occurred in Adana. A thorough search was made for meningococcus carriers, who were at once isolated, and diluted iodine or iodine-glycerin was applied to the nasopharynx until further examinations were negative. The absence of roads made laboratory tests and mass examination in rural communities difficult. Therefore it was decided to make general the application of antiseptics. But the application of irritating medicaments was not practical and did not give satisfactory results. As cases occurred in 1931 with the same severity in localities where such measures were taken the year before, another method was decided on. A solution of acriflavine hydrochloride, 1:250, was used, two or three drops in each nostril morning and night. It was easy to apply this method in schools and in the homes. In communities where it was possible to use this preventive measure generally, the disease has disappeared.

Marriages

TOSON OLCOTT SUMMERS, Surg., Lieut. Commander, U. S. Navy, to Miss Cynthia Mary Peacock of Derby, England, February 16.

HENRY LEVI DAVIS, Huntington Park, Calif., to Miss Frances Leon Gibson of Independence, Kan., January 29.

ELVIN L. SEDERLIN, Laramie, Wyo., to Miss Edythe Christine Cutter at Holmesville, Ohio, January 28.

ARTHUR C. DEAN, Hot Springs, S. D., to Miss Grace J. Hansen of Huron, at Omaha, recently.

LEONARD BEAVER ULSH, Philadelphia, to Miss Eleanor A. G. Grenover, recently.

Deaths

Albert Edward Flagstad ⊕ Minneapolis; University of Minnesota Medical School, Minneapolis, 1921; member of the Clinical Orthopedic Society and fellow of the American College of Surgeons; assistant instructor in orthopedics at his alma mater; on the staffs of the Gillette State Hospital for Crippled Children, St. Luke's Hospital, Bethesda Hospital, Midway Hospital and the Children's Hospital, St. Paul, and the Fairview Hospital, Minneapolis; on the visiting staff of St. Joseph's Hospital, St. Paul; aged 40; died, January 26, of lobar pneumonia.

William Henry Cantle ⊕ Mamaroneck, N. Y.; Cornell University Medical College, New York, 1901; member of the Associated Anesthetists of the United States and Canada; past president of the Westchester County Medical Society; served during the World War; formerly on the staffs of the United Hospital, Port Chester, and the New Rochelle (N. Y.) Hospital; aged 56; died, January 30.

Henry I. Raymond ⊕ Colonel, U. S. Army, retired, Berkeley, Calif.; Bellevue Hospital Medical College, New York, 1880; entered the army as an assistant surgeon in 1881 and was promoted through the various grades to that of colonel in 1915; was retired by the President in 1919, being 62 years of age; veteran of the Spanish-American War; aged 74; died, January 30, in the Letterman General Hospital, San Francisco.

Jesse Sumner Bragg, Manchester, N. H.; Medical School of Maine, Portland, 1905; member of the New Hampshire Medical Society, Maine Medical Association, New England Dermatological Society and the Radiological Society of North America; on the staff of the Hôpital Notre-Dame de Lourdes; aged 54; was killed, January 1, when his shotgun accidentally exploded.

Victor Henry de Somoskeoy, West Chester, Pa.; Detroit College of Medicine, 1905; served during the World War; public health director of Chester County; formerly health officer of Morgan County, Ill., and deputy state health officer of the tenth sanitary district of Maryland; aged 54; died, January 12, in the Chester County Hospital, of pneumonia.

Greyson Curtis Gardner, La Junta, Colo.; Indiana University School of Medicine, Indianapolis, 1925; member of the Colorado State Medical Society; served during the World War; on the staffs of the Atchison, Topeka and Santa Fe Railroad Hospital and the Mennonite Hospital and Sanitarium; aged 36; died, January 18, of tuberculosis.

Solon Rodney Towne, Omaha; Dartmouth Medical School, Hanover, N. H., 1875; member of the Nebraska State Medical Association; emeritus professor of hygiene, University of Nebraska College of Medicine; formerly on the staff of the Douglas County Hospital; aged 85; died, January 28, of bronchopneumonia.

Edward James Mahoney, Bedford, Ohio; Hahnemann Medical College and Hospital of Philadelphia, 1928; on the staffs of the Bedford (Ohio) Municipal Hospital and the Huron Road Hospital, Cleveland; aged 29; died, January 22, in the Springfield Lake Sanatorium, East Akron, of pulmonary tuberculosis.

John Abraham Freeborn ⊕ Fergus Falls, Minn.; Rush Medical College, Chicago, 1889; Bellevue Hospital Medical College, New York, 1892; served during the World War; on the staff of the George B. Wright Memorial Hospital; aged 67; died, January 25, in Rochester, of carcinoma of the pancreas.

Louis Grey Stirling, Baton Rouge, La.; Tulane University of Louisiana School of Medicine, New Orleans, 1894; member of the Louisiana State Medical Society; formerly member of the city council; on the staff of Our Lady of the Lake Sanitarium; aged 69; died, Dec. 19, 1931, of heart disease.

Marvin Lamar Parler, Wedgefield, S. C.; Medical College of the State of South Carolina, Charleston, 1900; member of the South Carolina Medical Association; on the staff of the Tuomey Hospital, Sumter; aged 52; was instantly killed, January 15, when his gun was accidentally discharged.

George Rosario Cusson ⊕ Berlin, N. H.; University of Vermont College of Medicine, Burlington, 1924; member of the New Hampshire Medical Society; president and formerly secretary of the Coos County Medical Society; aged 33; died, January 4, in Burlington, Vt., of chronic nephritis.

Frederick Murray Doyle, Chicago; Jenner Medical College, Chicago, 1903; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1904; member of the Illinois State Medical Society; aged 51; died, Dec. 8, 1931, of coronary embolism.

Alfred Pellar Webb, Atmore, Ala.; Medical College of Alabama, Mobile, 1896; member of the Medical Association of the State of Alabama; formerly chairman of the board of education; on the staff of the Atmore General Hospital; aged 58; died, January 11, of cerebral hemorrhage.

Louis Livingston Seaman ⊕ Bronxville, N. Y.; Jefferson Medical College of Philadelphia, 1876; Medical Department of the University of the City of New York, 1877; veteran of the Spanish-American and World wars; aged 80; died, January 31, in the Lawrence Hospital.

Arthur Ramsey Williamson, Pueblo, Colo.; Hahnemann Medical College and Hospital, Chicago, 1912; member of the Colorado State Medical Society; aged 50; died, January 7, in St. Mary Hospital, of streptococcic septicemia, streptococcic meningitis and otitis media.

Charles Holt McDonell, Winona, Minn.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1906; member of the Minnesota State Medical Association; on the staff of the Winona General Hospital; aged 55; died, January 12, of heart disease.

Joseph Grant Killgore, Vermilion, Ill.; Kentucky School of Medicine, Louisville, 1888; member of the Illinois State Medical Society; aged 65; died, Dec. 27, 1931, in a hospital at Paris, of injuries received in an automobile accident.

Charles C. Mandeville, Galion, Ohio; Starling Medical College, Columbus, 1893; served during the Spanish-American and World wars; aged 65; died, January 17, in the Good Samaritan Hospital, of carcinoma of the parotid gland.

Arthur B. Smith, Cleveland; New York Homeopathic Medical College and Hospital, 1897; aged 59; died, January 20, in St. John's Hospital, of injuries received when the automobile in which he was driving was struck by a train.

Elmer Clarence Byram, Okmulgee, Okla.; National University of Arts and Sciences, St. Louis, 1912; member of the Oklahoma State Medical Association; aged 49; died, January 23, in the City Hospital, of coronary thrombosis.

James C. May, York, Pa.; Jefferson Medical College of Philadelphia, 1881; member of the Medical Society of the State of Pennsylvania; for six years member of the school board; aged 74; died, January 19, of arteriosclerosis.

Edward N. Chastain ⊕ Butler, Mo.; Missouri Medical College, St. Louis, 1881; secretary and past president of the Bates County Medical Society; aged 75; died, January 5, of chronic myocarditis and aortic regurgitation.

Ida M. Kahn, Nanchang, China; University of Michigan Medical School, Ann Arbor, 1896; superintendent of the Women's and Children's Hospital; aged 58; died, Nov. 9, 1931, in a sanatorium at Shanghai.

William Warren Murphy, Sierra Madre, Calif.; Missouri Medical College, St. Louis, 1876; Bellevue Hospital Medical College, New York, 1884; aged 85; died, Nov. 21, 1931, of cerebral embolism and thrombosis.

Eugene Harold Brown ⊕ Pueblo, Colo.; Northwestern University Medical School, Chicago, 1911; served during the World War; on the staff of St. Mary's Hospital; aged 43; died, January 24, of pneumonia.

John West Benton, Ogdensburg, N. Y.; University of Pennsylvania School of Medicine, Philadelphia, 1886; for many years health officer of Ogdensburg; aged 67; died, January 25, of carcinoma of the stomach.

Howard Winslow Gibbs, Scranton, Pa.; Baltimore Medical College, 1913; member of the Medical Society of the State of Pennsylvania; served during the World War; aged 44; died, January 30, of carcinoma.

John Thomas Johnson, Taft, Calif.; Jefferson Medical College of Philadelphia, 1909; aged 52; died, Nov. 8, 1931, in the Cottage Hospital, of chronic interstitial nephritis and hypertension.

Charles W. Geel, Berlin, N. Y.; Albany Medical College, 1885; member of the Medical Society of the State of New York; aged 82; died, January 2, of acute dilatation of the heart.

Arch Sylvester Chapman ⊕ Fort Smith, Ark.; University of Nashville (Tenn.) Medical Department, 1909; aged 45; was found dead, Dec. 22, 1931, of a self-inflicted bullet wound.

Henry Egerton Day, Kingston, Ont., Canada; Queen's University Faculty of Medicine, Kingston, 1902; aged 54; was found dead in his garage, Dec. 14, 1931, of heart disease.

Martin V. Tyndall, Springfield, Mo.; Barnes Medical College, St. Louis, 1896; also a druggist; aged 67; died, January 21, of chronic nephritis and cerebral hemorrhage.

Edwin Russell Tuttle, Miami, Fla.; Hahnemann Medical College and Hospital, Chicago, 1888; aged 68; died, January 5, of cerebral hemorrhage, hypertension and myocarditis.

Joseph Dutra, Santa Maria, Calif.; Boston University School of Medicine, 1895; aged 72; died, Nov. 5, 1931, of cerebral hemorrhage and cardiovascular renal disease.

James M. McDowell, La Grange, Tenn.; University of Tennessee Medical Department, Nashville, 1880; aged 74; died, Dec. 3, 1931, of heart disease and nephritis.

William Anthony Hershiser, Oakland, Calif.; Cooper Medical College, San Francisco, 1891; aged 71; died, Nov. 2, 1931, in Turlock, of cerebral hemorrhage.

Frederick Harlan Hadley, San Francisco; Cooper Medical College, San Francisco, 1896; aged 61; died, Nov. 24, 1931, of cerebral hemorrhage and arteriosclerosis.

Benjamin W. D. Hill, Dawson, Texas; University of Tennessee Medical Department, Nashville, 1885; aged 68; died, January 1, in a sanatorium at Waco.

Andrew Johnson Waynick, Clarksville, Tenn.; University of Tennessee Medical Department, Nashville, 1885; aged 70; died, Nov. 23, 1931, of mitral stenosis.

Leander A. Dascombe ⊕ Skowhegan, Maine; Bellevue Hospital Medical College, New York, 1877; aged 78; died, Dec. 23, 1931, of cerebral hemorrhage.

Letitia L. Frantz, Lancaster, Pa.; Woman's Medical College of Pennsylvania, Philadelphia, 1884; aged 73; died, Dec. 18, 1931, of cerebral hemorrhage.

E. Davis Allen, Cortland, N. Y.; Eclectic Medical College of the City of New York, 1880; aged 76; died, January 21, of a self-inflicted bullet wound.

Walter Harvey Sullivan, Sausalito, Calif.; Cooper Medical College, San Francisco, 1883; aged 70; died, January 14, of an injury received in a fall.

Charles Chester Sperry, Marengo, Ill.; Chicago Medical College, 1874; aged 80; died, January 29, of chronic myocarditis and chronic nephritis.

Frank Edgar Dolson, Philadelphia; Jefferson Medical College of Philadelphia, 1901; aged 53; died, January 21, of carcinoma of the stomach.

Eliphalet N. Wright, Olney, Okla.; Albany (N. Y.) Medical College, 1884; aged 73; died, January 9, in Dr. Moorman's Sanatoria, Oklahoma City.

Thomas Ezra Rhodes, St. Louis; Barnes Medical College, St. Louis, 1910; aged 57; died, Dec. 28, 1931, in the Central Hospital, of empyema.

Joseph French Duncan, Etowah, Tenn.; University of Louisville (Ky.) School of Medicine, 1882; aged 72; died, Dec. 23, 1931, of septicemia.

Truman Huff Holmes, Bremerton, Wash.; Medical College of Ohio, Cincinnati, 1889; aged 65; died, January 7, of tumor of the brain.

Dudley Cureton Frise, Minneapolis; University of Illinois College of Medicine, Chicago, 1915; aged 44; died, January 10, of heart disease.

Preston A. Edwards ⊕ Nardin, Okla. (licensed, Oklahoma, under the Act of 1908); aged 71; died, January 27, of cerebral hemorrhage.

Sherrod W. Dutton, McCracken, Kan. (licensed, Kansas, 1901); aged 90; died, January 3, in Ness City, of arteriosclerosis.

William T. Hinds, Arab, Ala.; Medical College of Alabama, Mobile, 1890; aged 68; died, Dec. 21, 1931, of heart disease.

Correspondence

FLOWERS IN THE SICKROOM

To the Editor:—In THE JOURNAL, Dec. 5, 1931, page 1731, Dr. Stein asked why flowers are removed from the sickroom at night. In your answer you say: "The statement of one hospital superintendent that carbon dioxide is liberated is apparently not correct. Living plants absorb carbon dioxide and give off oxygen."

True enough, but this absorption of carbon dioxide stops in the dark, and cell respiration continues. Respiration is going on continually, in light and in darkness, and carbon dioxide is given off. It isn't true that the processes of giving off carbon dioxide and oxygen are reversed. Carbon dioxide is given off day and night, the rate being but little higher during the day or in the light than it is in darkness or at night. It varies somewhat more with change in temperature, increasing up to 40 C. Weight for weight, plants give off about the same amount of carbon dioxide as animals do. No patient in an average sized room could notice the effect of an average sized bouquet of flowers as far as the carbon dioxide is concerned. And the amount of oxygen given off during the day is also negligible as far as the patient is concerned.

A. P. SY, Buffalo.

Professor of Chemistry, University of Buffalo.

[NOTE.—Irrespective of whether the reaction is that of yielding oxygen or of yielding carbon dioxide, the amounts given off are surely not appreciable so far as any change in the oxygen-carbon dioxide ratio of a well ventilated hospital room is concerned.—ED.]

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

CHLORINE LEAKS IN CHLORINATION OF SWIMMING POOLS

To the Editor:—In connection with the chlorination of a swimming pool there sometimes occur leaks in the apparatus. The nature of the escaping gas makes it almost impossible for the attendant to do the necessary work to locate the leaks and, besides, constitutes a menace to him and to others. Can you advise me as to what means may be taken to safeguard the life and health of the attendant and at the same time permit him to do the required work in the presence of escaping chlorine gas? If there is no satisfactory measure other than the use of a gas mask, can you inform me where such a mask may be obtained and advise me concerning its probable length of serviceable life?

SHATTUCK W. HARTWELL, M.D., Muskegon, Mich.

ANSWER.—Any sustained and substantial leak of chlorine in connection with the chlorination of swimming pool waters indicates defective apparatus. Modern chlorinating machinery, when properly operated, prevents any leaks in harmful concentrations. The wearing of a gas mask around a swimming pool is poor psychology, if worn in view of the bathers. Prejudice against chlorination is thus created, and patronage is likely to diminish. For this reason the point of first attack in control should be the apparatus itself. If, for some practical reason, leaks cannot be eliminated by tightening the apparatus, a gas mask is necessary. Chlorine is an immediate irritant to the respiratory tract when the concentration is no higher than 15 parts per million parts of air. Prolonged exposure to an atmosphere containing 2 parts of chlorine will eventuate in some damage. This amount is lower than that giving rise to any odor of chlorine.

Suitable gas masks may be procured from the Mine Safety Appliances Company, Braddock, Thomas and Meade streets, Pittsburgh. In addition, extensive information, including many other sources of gas masks, may be obtained from the National Safety Council, 20 North Wacker Drive, Chicago.

With reasonable care, the serviceable length of life of an occasionally used mask may be one year, although replacement of certain parts may be required.

DANGER OF SYPHILIS TO ATTENDING PHYSICIAN

To the Editor:—A member of my class in the school of medicine, while attending an autopsy on a congenital syphilitic fetus, Oct. 10, 1931, had a small drop of the bloody water splashed into his eye. The incident was not noticed by the instructor, and the student thought little of it at the time. However, about two hours later he began to worry and washed his eye with a dilute solution of a germicide. He went to the director of the clinic for advice. He was given an injection of 0.5 Gm. of neoarsphenamine late that same afternoon, or about six hours after the accident. Two days later he was given an injection of 0.4 Gm. of arsphenamine, and one week following this, another injection of 0.4 Gm. of arsphenamine. At no time did a lesion of any sort develop on the conjunctiva. The Wassermann and Kahn tests were done, December 18, or about ten weeks following the accident, and both were negative. What is the possibility that infection actually occurred? Was the treatment given sufficient to abort the possible infection? Should this student have the Wassermann or Kahn tests repeated at intervals? Please omit name.

M.D., Missouri.

ANSWER.—Three possibilities must be considered:

1. The organisms were dead in the fetus or so weakened by the water or the injected germicidal solution that they could not infect.
2. The infection took place but was overcome by the treatment.
3. The treatment was sufficient to delay development of the infection but not enough to cure it.

It is to be hoped that the fact agrees with either the first or the second of these possibilities; but it must be granted that the third is possible, and therefore the case should be watched carefully for the rest of the year. A clinical examination with particular attention to the eye, the mouth and the anogenital region, and serologic tests should be made once a month. If nothing develops in one year, we believe that the danger is past. The first possibility is probably the true one.

IRRADIATION IN CARCINOMA OF BREAST

To the Editor:—In scirrhous carcinoma of the breast, is it advisable to use preoperative and postoperative radiation, as recommended in other types of carcinoma of the breast? Please omit name.

M.D., California.

ANSWER.—The scirrhous type is by far the most common form of breast cancer. Except in hopelessly inoperable stages of the lesion, i. e., ulceration of the skin with infection, the same treatment routine is applicable, a combination of surgery and irradiation. Preoperative irradiation, originally advised on the basis that a preliminary lymphatic block is produced, is no longer advised. Postoperative irradiation, beginning about ten days after operation, is necessary and is undoubtedly responsible for the relatively high percentage of present-day cures. It is important to remember that the scirrhous form, though less malignant than the medullary, is still a malignant tumor and that when axillary lymphatics are involved in this type of the disease (scirrhous) the incidence of early recurrence is about 80 per cent.

TREATMENT OF EXFOLIATIVE DERMATITIS

To the Editor.—I should like to know the treatment of dermatitis exfoliativa and the rationale of giving splenic extract, if there is any. Please omit name.

M.D., Arizona.

ANSWER.—The first indication is rest in bed, which also affords protection from chilling. Colloid baths may be given, one or more a day according to the response on the part of the patient; the water should be kept at an even temperature (about blood temperature or a little below) and the patient protected from drafts by blankets over the tub. If necessary, an ice bag should be used on the head. When the patient emerges from the bath, the skin should be dabbed partly dry and an ointment (10 per cent boric acid in petrolatum or ointment of rose water) applied immediately. The bath is made by boiling three cupfuls of oatmeal to a mush and putting it in a gauze bag and then into the tubful of warm water, in which a cupful of sodium bicarbonate has already been dissolved. The bag of oatmeal should be squeezed gently and the water stirred with it.

Engman uses the powder bath, keeping the patient naked in a bed full of talcum powder, with plenty of powder dusted on the skin. For a day or so this may be uncomfortable, but then the patient comes to like it and improves.

For nonarsphenamine cases, the exception nowadays, quinine in large doses is recommended. Acetylsalicylic acid or pilocarpine may be useful. For the much commoner cases due to overdosage with arsphenamine or its modifications, sodium thiosulphate intravenously is the chief remedy, the drug being carefully prepared for intravenous use dissolved in a small amount of sterile distilled water. From 0.1 to 0.3 Gm. once a day is given at first; the dose is gradually increased to 1 Gm. daily and is then given once every other day. Sometimes this treatment disagrees and must be discontinued. Roentgen rays in fractional doses, one fourth of an erythema dose once a week, are highly recommended by Andrews, care being taken that not too large a part of the surface of the body is treated on any one day. The blood count, particularly the white cell count, should be carefully watched. If a leukopenia appears, it may be due to an overdose of rays. Unfiltered rays are used.

The rationale of the injection of splenic extract is not well understood nor has the product been standardized. The spleen belongs to the reticulo-endothelial system, and certain extracts made from it seem to have a marked effect in supplying something necessary to the prevention of infection in splenectomized animals and human beings. It also seems at times to be effectual in the treatment of anemias and other general disorders. In skin disease, such as eczema and urticaria, it has been used most effectually in the various forms of sensitization. Exfoliative dermatitis belongs to this group, and it might be expected to have a beneficial effect. Whether this action is that of a foreign protein or a hormone, or whether it is due to the nuclein so plentiful in the spleen is not established.

POSSIBLE TABES OR CEREBROSPINAL SYPHILIS

To the Editor:—About two months ago, I saw a young man at his home, evidently in severe pain. His hands were pressed tightly together on his abdomen just to the left of the end of the sternum. He complained of severe nonradiating pain in this area. While I stood there, questioning him, the attack suddenly disappeared, leaving absolutely no tenderness. When he could speak more freely, he told me that this had been the second attack he had had of this nature. The seizures came on suddenly, gradually growing in intensity until the pain was almost unbearable, nonradiating and localized to a small area in the upper portion of the abdomen just to the left of the line of the sternal border and just below the lower ribs. After the pain disappears, there is no tenderness left or any local symptoms. I found that the bowels were constipated and for the last two months the patient had been eating irregularly, his meals being mostly cold beer, sandwiches and salted peanuts. He was 33 years of age, well built and had always been perfectly well. He gave an absolutely negative past history of stomach disorders and was physically normal on examination. I made a diagnosis of acute gastritis, put him on a suitable balanced die, emptied his bowels and gave him a digestive mixture. The following week he was all right, felt fine and had no further attacks. I again examined the heart and abdomen, and could find nothing. I happened to think of Osler's dictum, "Know syphilis and you will know disease," so I asked the patient whether he had ever had a chancre. He stated that he had, about a year before. He had gone to a doctor who had put some powder on the chancre and had told the patient that the disease would never bother him in his blood. Aside from a somewhat sluggish reaction of the pupils to light, I could not find any external evidence of syphilis, and he stated that there had not been any symptoms. I did not do a lumbar puncture but took a Wassermann test, which showed a reaction of 4 plus for both antigens. Do you think that these attacks of pain that he had could have been tabetic? Also, please inform me of the approved system of treatment which I should use here for the syphilitic infection, especially as to how long the treatment should continue and how long this patient should be kept under observation after the Wassermann reaction is made negative. I do not wish to do a puncture on this man unless you think it necessary, as he is sensitive to pain and faints every time a needle is used under his skin. Harold D. Sehl, M.D., Clarkes Mills, N. Y.

Answer.—In the absence of more definite signs, such as loss of deep reflexes, incoordination and a positive Romberg sign, a positive diagnosis of tabes dorsalis is not justified. It is possible, however, that the attacks are of the nature of gastric crises resulting from syphilis of the nervous system and that the disease may evolve more typically. Since no antisyphilitic treatment has been administered, active courses should be instituted, starting with compounds of mercury and possibly of bismuth, arsphenamine being given later. A lumbar puncture may be postponed until these preliminary treatments have been administered but should then be done in order to establish or rule out involvement of the central nervous system and furnish a guide to subsequent treatment. Under this heading will have to be considered some form of fever therapy and the use of tryparsamide as well as further active antisyphilitic remedies. The puncture should not be delayed merely because the Wassermann reaction of the blood has not become negative but should be done shortly after the completion of the first course of antisyphilitic remedies.

RABIES VACCINES AND PASTEUR TREATMENT

To the Editor:—Please give me the comparative values of rabies vaccine and the Pasteur treatment in the prevention of rabies. This city is called on to do considerable work along this line and the difference in cost between the standard rabies vaccine and the Pasteur treatment is considerable. P. R. Outlaw, M.D., El Paso, Texas.

Answer.—So far as the available evidence goes, the newer rabies vaccines, including those made of killed virus, are about as efficient as the old Pasteur treatment, which utilized a living attenuated virus.

USE OF COCAINE FOR LOCAL ANESTHESIA IN CYSTOSCOPY

To the Editor:—The free use of cocaine solutions by ear, nose and throat specialists has caused me to wonder whether urologists do not exaggerate the dangers of this drug as a urethral injection. The remark of Keyes that "cystoscopy as usually performed is a scandalously painful operation" seems borne out by the obvious apprehension with which male patients view the procedure. I should greatly appreciate an authoritative reply to the following questions: Is cocaine generally condemned by the best authorities as a local anesthetic for the urethra, or is its use permissible in suitable amounts and with caution? At the Mayo Clinic I observed that a 1 per cent solution of cocaine hydrochloride was used for cystoscopies, apparently as a routine. Do you think that any danger attends this? What volume of a 1 per cent solution of cocaine hydrochloride could one inject into a man's urethra and bladder with reasonable safety preliminary to passing sounds, cystoscopes and similar instruments? Would subacute or chronic urethritis materially increase the danger of toxic absorption of such an injection? Is butyn, isocaine or any other cocaine substitute (excluding procaine hydrochloride, which seems of little value) efficacious and safe for urethral injection? Please omit name.

M.D., Utah.

Answer.—The best urologic authorities are divided as to the risk incurred in the injection of cocaine into the male urethra. Keyes and Randall warn against its use, while Walthers and the staff of the Mayo Clinic report that they have used it for years without untoward effect.

Thirty cubic centimeters of a 1 per cent solution may be used with reasonable safety preliminary to the passage of sounds or cystoscopes, provided the solution is made up fresh for each case. This can readily be done by dissolving two 2¼ grain (0.146 Gm.) tablets in 30 cc. of water. There are some who believe that some of the toxic properties in cocaine solutions are the result of a fungus growth which appears in most stock solutions in a very short time. Care should be taken to inject the solution slowly and to avoid the exertion of undue hydrostatic pressure, as rupture into the small blood vessels occurs easily.

Subacute or chronic urethritis has never been noted to increase the danger of toxic absorption.

Butyn, isocaine and other cocaine substitutes are not as efficacious as cocaine, according to clinical experience, and it is doubtful whether they are any safer for urethral injections.

Following instrumentation, either immediate or delayed, cocaine solution should not be injected into the urethra, as traumatized surfaces induce rapid toxic absorption.

REACTION TO SENSITIZATION

To the Editor.—A farmer, aged 33, consulted me regarding spells of dizziness and nausea which come on only when he does work in his barn. He has been troubled for about four weeks, never before. He states that he feels perfectly well in any other place, has a good appetite and has never been ill in his life that he can recall. He can do his work without any difficulty whatever, with the exception of indoor work in his barn. He says that in a few minutes after entering his barn, perhaps only to put a harness on a team, he begins to feel dizzy and sick and is obliged to get out into the fresh air, where in a short time he feels all right again. So far as he knows, there are no chemicals or fumes of any kind in the barn other than those from the animals and their droppings. I have examined him carefully several times and cannot find anything abnormal. The urine, the blood and the special senses are normal, and the mentality also apparently is normal. I suggested that he try some oil of cloves in petrolatum to be smeared in the nostrils just before entering the barn. He tells me that this prevents the diziness for a while, till the aroma of the cloves is dissipated.

A. H. Campbell, M.D., Rocanville, Sask.

Answer.—The spells of vertigo and nausea, which occur only when the patient is working in the barn, may be explained in either of two ways: 1. They may be an evidence of functional disorder; the odor of the barn and its contents may cause the patient to feel nauseated and dizzy. This theory, however, is lessened in value by the fact that the duration of symptoms is only four weeks, whereas in all probability such contact has existed from childhood. 2. The symptoms may be due to an allergic manifestation; the odor or inhalation of animal dander from the barn contents may cause a temporary disorder of the brain. Just what the nature of this condition is can only be surmised, as no pathologic reports exist. However, it is known that allergy in general is characterized by one or both of two conditions: spasm of smooth muscle or increased capillary permeability with resultant localized edema. The latter condition would be compatible with symptoms such as are noted here and could come and go rapidly just as the ordinary hive, which is a localized area of edema, may come and go quickly. Whether the condition is allergic or not will depend on further information, such as (1) the presence of some other allergic condition in the patient; for example, asthma, hay fever, urticaria or migraine; (2) a history of some allergic condition in the family; (3) the presence of blood eosinophilia, or (4) positive skin reactions, although these probably would not be obtained. An important clinical test would be to have the patient come in contact with the various contents of the barn, such as horses or cattle, separately, inside and outside the barn. As for treatment, in addition to the measures described the patient might cover his nostrils and mouth with a wet piece of cloth or gauze so that inhalation of the obnoxious odor or dander would be difficult.

UNUSUAL PURPURIC LESIONS OF EXTREMITIES

To the Editor:—A woman, aged 60, with an irrelevant history, six weeks ago felt a severe pain, like the sting of a bee, on the left ankle, anterior to the external malleolus. This was followed at once by an intense itching, not relieved for several minutes, and this in turn was followed by a severe burning sensation. Shortly, there appeared a hemorrhagic area measuring about 1 by 2 inches. For days, at intervals of a few hours and lasting for several minutes, the cycle of sting and itching and burning was repeated. Now the skin over the area has become thickened and brownish, almost wartlike, and the same cycle as before mentioned is repeated several times a day. Lately other hemorrhagic areas, of various sizes, have appeared below the knee, with slight itching and burning, to disappear promptly while others appear. Kindly indicate the name of the malady and suggest treatment. Please omit name.

M.D., Indiana.

Answer.—The greatest obstacle to a helpful answer to this question is the difficulty that is always encountered in visualizing a skin lesion from any written description. The best that can be done is to suggest some possibilities.

The picture could be explained as due to one of the purpura group, the local manifestation of which may vary considerably. A form of simple purpura is observed in those past middle life, especially in those with varicose veins or other circulatory disturbances in the lower extremities, which has been designated as purpura senilis. In this condition purpuric spots appear usually just above the ankle and and on the lower leg. The spots may remain for long periods, and leave pigmented areas. There is a possibility also of a purpura of more serious significance, and the patient should be examined for evidence of systemic disease.

Urticaria also may show a hemorrhagic tendency. Erythema nodosum must also be considered but appears unlikely from the description, as the lesions are red, later becoming darker, but are not hemorrhagic. A form of erythema multiforme, erythema perstans, may show nodules and be itchy, but this is also not hemorrhagic.

Embolic phenomena are a possibility that must be ruled out. The treatment is that of the causative pathologic process.

TREATMENT OF FREQUENT URINATION AND BURNING SENSATION

To the Editor:—A woman, aged 39, has had burning and frequency of urination beginning 5 years ago. She has one child, aged 12, who was delivered instrumentally. A cystocele was repaired three years ago, after which her bladder symptoms disappeared for three months. She had a suprapubic drainage and 1:1,500 silver nitrate irrigations one year ago, following which her symptoms disappeared for a few months and gradually returned. At this operation it was found that she had a small inflamed bladder. She has had many cystoscopic and urine examinations, which have always been negative. She is a druggist's wife and has tried every urinary antiseptic known without benefit. Bladder irrigations with boric acid, and mild silver protein or mercurochrome-220 soluble in the bladder give some temporary relief. She insists there is something wrong in the urethra, but examinations reveal nothing. The former cystocele is well repaired. There is a small rectocele. What do you advise in the line of further treatment?

Chester A. Clark, M.D., Morley, Mich.

Answer.—In cases of contracted bladder that resist treatment, as apparently this one has, one would think of the possibility of submucous infiltration of the bladder or what is often called elusive ulcer. Tuberculosis might be thought of, but this should have been picked up in the examination of the patient. If an ulcer is the cause of the symptoms, the treatment would necessarily depend on the location of the ulcer.

EXCESS HAIR ON GIRL'S BODY

To the Editor:—A girl, aged 5 years, of normal height, weight and sexual development, presents a heavy growth of fine hair on the forearms, back and legs. This condition has been getting more marked for the past six months. The past medical history is negative except for chronic tonsillitis. Is this a sign of glandular dysfunction? What treatment do you advise?

Lewis E. Etter, M.D., Warrendale, Pa.

Answer.—This child probably has some endocrine disturbance. The two glands most liable to be at fault in such cases are the pineal and the suprarenal cortex. A large majority of patients having a teratoma of the pineal also experience precocious puberty. This is accompanied by some increase in the amount of body hair, particularly the pubic and axillary hair, and, of course, by precocious development and function of the genital apparatus. Tumors of the suprarenal cortex more frequently give rise to, or at least are accompanied by, an increase in the amount of hair on the body and face. When these occur in young children they are also accompanied by a precocious growth of the body and genitalia.

One can only suggest that this child be kept under observation, having in mind particularly the possibility of disturbance in the pineal or the suprarenal cortex. No treatment can be suggested at this time. Frequently, cases of abnormal development of hair clear up without treatment.

SHOES FOR CLUBFOOT

To the Editor:—Can you refer me to a manufacturer of shoes for use in convalescence from infantile congenital clubfeet; i. e., shoes with the front part abducted instead of adducted in the common way of children's shoes? I. Sabel, 1015 Chestnut Street, Philadelphia, makes such shoes but refuses to furnish a single clubfoot shoe with a normal mate without a premium of $1.50 over the charge of $7 for two clubfoot shoes. This seems to me not to meet the need of patients with clubfoot, as more than half of them are one-sided cases.

M.D., Michigan.

Answer.—The firm mentioned is used by many orthopedic surgeons. It does seem a little strange to be charged $7 for two clubfoot shoes and $1.50 extra for mismating. When a firm mismates two pairs of shoes, it returns the two others to the factory for remating and, therefore, must make this charge. It is stated on good authority that 57 per cent of cases are unilateral.

INTOXICATION FROM LACQUER AND DUCO

To the Editor—Have there been cases reported of toxic effects from Duco or other lacquers? A patient who suffers with weakness, nervousness and loss of weight feels that his condition is due to inhaling such materials.

M.D., Illinois.

Answer.—The term "Duco" applies only to certain products of the Du Pont Company. Duco consists largely of the acetates of amyl, butyl and ethyl, diluted with denatured alcohol, toluene, butyl alcohol and amyl alcohol. From the point of view of its effects on health it probably does not differ greatly from the pyroxylin lacquers that have been used for many years. Cases of poisoning with such lacquers have been reported in various periodicals. Most of the constituents of lacquers are irritants to the respiratory tract. It is conceivable that the symptoms to which the patient refers may be due to toxic action of some of the ingredients that have been listed. However, it is important to determine the exact content of the lacquer used, whether or not the condition originated during or shortly after exposure, and other factors that are of importance in relationship to industrial disturbances.

PREVENTION OF TRANSMISSION OF RINGWORM

To the Editor:—We have, at our plant, the question of disinfecting rubber boots so as to render them safe for reissue. I desire to safeguard especially against the transmission of tinea infections from one person to another. What is the best method of accomplishing this purpose?

E. C. McCulloch, M.D., Staten Island, N. Y.

Answer.—The solution used for preventing the spread of ringworm in schools, solution of chlorinated soda, diluted to contain 1 per cent of sodium hypochlorite, may be successful, or a 5 per cent solution of thymol in alcohol. The boots should be rinsed afterward; in case of the hypochlorite treatment, the rinsing should be with water; in case of thymol, which irritates some skins, the excess should be removed from the boots by rinsing with alcohol.

AREAS OF GIANT RAGWEED GROWTH

To the Editor:—Will you please advise me as to the specific localities in the United States, especially in the Eastern section, that are free from giant ragweed? I have heard that Montauk Point, Long Island, N. Y. is. Can you confirm this?

Emily C. Lacy, Annapolis, Md.

Answer.—It is altogether likely that giant ragweed is absent in the vicinity of Montauk Point, as this species is not usually found in sandy soil. This plant thrives best in the rich, alluvial soil of river bottom land. It is not found at all on the Pacific Coast and grows sparingly in the Mountain states. Its northern range does not extend as far as that of short ragweed (Ambrosia elatior). It is fairly common in southwestern Ontario but is not found at Toronto. Although common at Buffalo, only stray specimens are found east of the Connecticut River and there is none along the coast, from Charleston, S. C., to Miami.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

American Board of Obstetrics and Gynecology: Written examinations will be held in nineteen cities of the United States and Canada, March 26. The general, oral and clinical examination will be held in New Orleans, May 10. Sec., Dr. Paul Titus, 1015 Highland Building, Pittsburgh.

Arizona: Phoenix, April 5-6. Sec., Dr. B. M. Berger, 12 N. Central Ave., Phoenix.

California: *Reciprocity.* Los Angeles and San Francisco, March 16. Sec., Dr. Charles B. Pinkham, 420 State Office Bldg., Sacramento.

Colorado: Denver, April 6-9. Sec., Dr. Wm. Whitridge Williams, 422 State Office Bldg., Denver.

Connecticut: *Homeopathic.* New Haven, March 8. Sec., Dr. Edwin C. M. Hall, 82 Grand Avenue, New Haven. *Regular.* Hartford, March 8-9 *Endorsement.* March 22. Sec., Dr. Thomas P. Murdock, 147 W. Main St., Meriden.

Idaho: Boise, April 5. Comm. of Law Enforcement, Hon. Emmitt Pfost, Boise.

Illinois: Chicago, April 12-14. Supt., Mr. Paul B. Johnson, Springfield.

Maine: Portland, March 8-9. Sec., Dr. Adam P. Leighton, Jr., 192 State St., Portland.

Massachusetts: Boston, March 8-10. Sec., Dr. Stephen Rushmore, *144 State House, Boston.*

Minnesota: *Basic Science.* Minneapolis, April 5-6. Sec., Dr. J. C. McKinley, 126 Millard Hall, University of Minnesota, Minneapolis.

Montana: Helena, April 5. Sec, Dr. S. A. Cooney, Power Block, Helena.

New Hampshire: Concord, March 10-11. Sec., Dr. Charles Duncan, Concord.

New Mexico: Santa Fe, April 11. Sec., Dr. P. G. Cornish, Jr., 221 W. Central Ave., Albuquerque.

Oklahoma: Oklahoma City, March 8-9. Sec., Dr. J. M. Byrum, Shawnee.

Rhode Island: Providence, April 7-8. Dir., Dr. Lester A. Round, 319 State Office Building, Providence.

West Virginia: Charleston, March 22. Sec, Dr. W. T. Henshaw, Charleston.

Indiana Reciprocity Report

Dr. William R. Davidson, secretary, Indiana State Board of Medical Registration and Examination, reports 43 physicians licensed by reciprocity with other states during 1931. The following colleges were represented:

College	Year Grad.	Reciprocity with
LICENSED BY RECIPROCITY		
College of Medical Evangelists	(1930) Michigan,	Tennessee
Chicago College of Medicine and Surgery	(1913)	Illinois
Hahnemann Medical College and Hospital, Chicago	(1889)	Illinois
Loyola University School of Medicine	(1926), (1928)	Illinois
Northwestern University Medical School	(1930)	Illinois
Rush Medical College	(1923), (1929)	Illinois
University of Illinois College of Med.	(1929), (1930, 2)	Illinois
State University of Iowa College of Medicine	(1902)	Iowa
University of Louisville Medical Department	(1915)	Kentucky
University of Louisville Sch. of Med.	(1925), (1926), (1929)	Kentucky, (1929) Ohio
College of Physicians and Surgeons of Baltimore	(1891)	N. Carolina
Johns Hopkins University School of Med.	(1917), (1927)	Maryland, (1926) Pennsylvania
Detroit College of Medicine and Surgery	(1927)	Michigan
University of Michigan Homeopathic Medical School	(1913)	Michigan
University of Michigan Dept. of Med. and Surg.	(1914)	Michigan
University of Michigan Medical School	(1924)	Maryland, (1925), (1926), (1927), (1929) Michigan
University of Minnesota Medical School	(1927)	Minnesota
Syracuse University College of Medicine	(1920)	New York
Eclectic Medical College, Cincinnati	(1929)	Kentucky
Ohio State University College of Medicine	(1924), (1926)	Ohio
University of Cincinnati College of Medicine	(1927)	Ohio
Jefferson Medical College of Philadelphia	(1928)	Penna.
Temple University School of Medicine	(1928)	Ohio
University of Nashville Medical Department	(1909)	Alabama
Milwaukee Medical College	(1910)	Wisconsin
University of Toronto Faculty of Medicine	(1921)	Illinois, (1923) Michigan
University of Athens School of Medicine, Greece	(1915)	W. Virginia

Hawaii October Examination

Dr. James A. Morgan, secretary, Hawaii Board of Medical Examiners, reports the written examination held at Honolulu, Oct. 12-15, 1931. The examination covered 10 subjects and included 55 questions. An average of 75 per cent was required to pass. Six candidates were examined, all of whom passed. The following colleges were represented:

College	Year Grad.	Per Cent
PASSED		
Indiana University School of Medicine	(1930)	82.2
State University of Iowa College of Medicine	(1930)	76.4
University of Louisville Schoool of Medicine	(1931)	79.9
University of Michigan Medical School	(1930)	78.7
Washington University School of Medicine	(1930)	84.3
University of Vermont College of Medicine	(1931)	82.1

Arkansas November Report

Dr. Sam J. Allbright, secretary, State Medical Board of the Arkansas Medical Society, reports the written examination held at Little Rock, Nov. 10-11, 1931. The examination covered 12 subjects and included 120 questions. An average of 75 per cent was required to pass. One candidate was examined and passed. Eleven physicians were licensed by reciprocity with other states. The following colleges were represented:

College	Year Grad.	Per Cent
PASSED		
Barnes Medical College, St. Louis, Mo.	(1899)	79

College	Year Grad.	Reciprocity with
LICENSED BY RECIPROCITY		
Rush Medical College	(1897) California, (1930)	Illinois
Tulane University of Louisiana School of Med.	(1930, 2)	Louisiana
Washington University School of Medicine	(1929), (1930)	Missouri
University of Nashville Medical Department	(1908)	Tennessee
University of Tennessee College of Medicine	(1925)	Louisiana, (1916), (1930), (1931) Tennessee

Ohio October Report

Dr. H. M. Platter, secretary, Ohio State Medical Board, reports 34 physicians licensed by reciprocity with other states and 3 physicians licensed by endorsement of credentials at a meeting held Oct. 6, 1931. The following colleges were represented:

College	Year Grad.	Reciprocity with
LICENSED BY RECIPROCITY		
University of Colorado School of Medicine	(1929)	Colorado
Howard University School of Medicine	(1930)	Maryland
Rush Medical College	(1926)	Maryland
Indiana University School of Medicine	(1910), (1925)	Indiana
State University of Iowa College of Med.	(1928), (1930)	Iowa
University of Kansas School of Medicine	(1930)	Kansas
Kentucky School of Medicine	(1893)	W. Virginia
University of Louisville School of Medicine	(1928)	Kentucky
Baltimore Medical College	(1905) Pennsylvania, (1907)	Colorado
Johns Hopkins University Schoool of Med.	(1928), (1931)	Maryland
University of Michigan Medical School	(1919)	New York, (1927), (1928, 2), (1929, 2), (1930, 4) Michigan
St. Louis University School of Medicine	(1930)	Missouri
New York Homeopathic Medical College and Hospital	(1906)	New York
Hahnemann Medical College and Hospital of Philadelphia	(1929), (1930, 2)	Penna.
Temple University Schoool of Medicine	(1917), (1927)	Penna.
Woman's Medical College of Pennsylvania	(1908)	Penna., (1910) Maryland
University of Toronto Faculty of Medicine	(1923)	Michigan

College	Year Grad.	Endorsement of
LICENSED BY ENDORSEMENT		
University of Michigan Medical School	(1930)	N. B. M. Ex.
Columbia University College of Phys. and Surgs.	(1929)	N. B. M. Ex.
Woman's Medical College of Pennsylvania	(1930)	N. B. M. Ex.

District of Columbia Reciprocity Report

Dr. W. C. Fowler, secretary, Commission on Licensure, reports ten candidates licensed by reciprocity with other states from Jan. 30 to Dec. 9, 1931. The following colleges were represented:

College	Year Grad.	Reciprocity with
LICENSED BY RECIPROCITY		
College of Medical Evangelists	(1915) Maryland, (1917)	California
University of Colorado School of Medicine	(1903)	Maryland
George Washington University Medical School	(1928)	Maryland
Baltimore University School of Medicine	(1896)	Maryland
College of Physicians and Surgeons of Baltimore	(1893)	New York
Maryland Medical College, Baltimore	(1912)	Maryland
University of Michigan Medical School	(1922)	Michigan
Medical College of Virginia	(1929)	Virginia
Osteopath		Iowa

Montana October Report

Dr. S. A. Cooney, secretary, Montana State Board of Medical Examiners, reports the written examination held at Helena, Oct. 6-7, 1931. The examination covered 10 subjects and included 50 questions. An average of 75 per cent was required to pass. Five candidates were examined, all of whom passed. Two physicians were licensed by reciprocity with other states. The following colleges were represented:

College	Year Grad.	Per Cent
PASSED		
Emory University School of Medicine	(1926)	83.9
Rush Medical College	(1931)	85.7
University of Illinois College of Medicine	(1931)	85.3
University of Michigan Medical School	(1930)	84.1
University of Oregon Medical School	(1931)	83.9

College	Year Grad.	Reciprocity with
LICENSED BY RECIPROCITY		
University of Michigan Medical School	(1926)	Michigan
Columbia University College of Phys. and Surgs.	(1905)	Iowa

Book Notices

History of Medicine in the United States. By Francis R. Packard, M.D. In two volumes. Cloth. Price, $12 per set. Pp. 1323, with 103 illustrations. New York: Paul B. Hoeber, Inc., 1931.

Previous to the publication of this contribution the foremost history of medicine in America was the book by Mumford. The story of medicine in America is some 200 years old. Much of our development is the reflection of work done abroad, but there has been a melting pot of science as well as a melting pot of races and nations—to the advantage of medicine. Dr. Packard has not attempted an evaluation of the recent development of foundations for research and great institutes for medical education. His consideration practically ends with the beginning of the present century.

Quite recently many of the states have been developing individual histories which are exceedingly valuable. These are reflected in Dr. Packard's book. In his first volume he considers medical legislation, education and hospitals during the earliest period, the medical profession in the war for independence and the history of the medical department of the army up to the close of the Spanish-American War. The second volume provides a history of the medical department of the United States Navy and of the medical schools founded during the first half of the nineteenth century. The author then outlines the development of medical practice and education in some of the states and concludes with chapters on foreign influences in American medicine, notable events in American medicine and surgery, and the beginnings of specialism in America. There are numerous appendixes of interest, including particularly reprints of early lectures and documents, a list of the surgeon generals of the United States Army, a discussion of the ether controversy, and a record of the *American Journal of the Medical Sciences* and the *Boston Medical and Surgical Journal*. There are sections on homeopathic medical colleges and on women in medicine, on physiomedical and electric colleges, and finally a bibliography and a well prepared index.

It is safe to say that what Dr. Packard has here contributed is excellent. The reader should not, however, consider the book as in any sense of the word an adequate history of medicine in the United States. There is so much missing in so many fields that space is not available to begin to list what is absent. For instance, the section on the history of medicine in Illinois, beginning on page 850, is inadequate from numerous points of view. If Illinois, which has had so much consideration by medical historians, is so poorly handled, other states must suffer even more. The part played by the American Medical Association in the development of American medicine has either been intentionally minimized or else is sadly unappreciated by Dr. Packard.

These two volumes may therefore be considered a collection of interesting notes on the history of medicine in America, reflecting Dr. Packard's personal interests, and beyond that in no sense of the word an adequate record of events from the point of view either of completeness or of historical perspective. It is idle to speculate as to the reasons for the failure of Dr. Packard to provide an adequate story, but the fault must lie in a failure to appreciate American medicine as a whole. Dr. Packard himself recognizes in his preface the unevenness of the material and the numerous omissions. However, in view of this recognition it might have been better to reflect in the title of the work its actual character as a collection of essays rather than a history.

Opuscula selecta Neerlandicorum de arte medica. Fasciculus nonus quem curatores miscellancorum quae vocantur Nederlandsch Tijdschrift voor Geneeskunde. Leeuwenhoek. Collegerunt et ediderunt Amsterdam Sumptibus Societatis. Cloth. Pp. 145, with illustrations. Amsterdam: Sumptibus Societatis, 1930.

In the preface, G. van Rijnberk describes how it has come about that certain of the earliest scientific letters of van Leeuwenhoek, the great microscopist, 1632-1732, which were thought to be lost, at length came to light. E. C. van Leersum reviews the letters of van Leeuwenhoek, "the pioneer of the microscope," on his varied observations to the Royal Society in London. Clifford Dobell, who was the first to draw attention to the existence of the letters published in this volume, contributes a valuable historical and bibliographic notice. J. G. de Lint writes an interesting chapter about the portraits of van Leeuwenhoek, a sturdy figure, some of which are reproduced at the end of the volume. The original Dutch text and the English translation of the hitherto unpublished letters by van Leeuwenhoek forms the main part of the book. There are facsimile reproductions of several of the letters and also of drawings by their author. The book will interest greatly students of the history of medicine and of science in general. It is an appropriate and important addition to the valuable series of historical textbooks in which it is published.

Industrial Hygiene for Engineers and Managers. By Carey P. McCord, M.D., Medical Director, The Industrial Health Conservancy Laboratories, Cincinnati, Ohio. Assisted by Floyd P. Allen, M.D. Cloth. Price, $5. Pp. 336, with 63 illustrations. New York: Harper & Brothers, 1931.

As stated in the introduction to this extraordinarily fine contribution to the subject of occupational disease, the application of adequate industrial measures is believed to be now limited to less than 5 per cent of this country's industries. Such knowledge as is now available has grown out of contributions by various governmental, social and trade bodies. The average physician has some general knowledge of the subject, but his knowledge is seldom systematized so as to be directly applicable to any given industry. The material contained in the contribution by Dr. McCord and Allen has been the basis of a course given to students in the Engineering College of the University of Cincinnati. Beginning with the introduction, which outlines the character of the problem, sections are devoted to emergency aid for the industrially injured, and to infection and disinfection. Then come several classifications of occupational diseases, with a long list of hazards presented in alphabetical order, and a long list of trades and industries in which occupational diseases may arise. The material is also listed according to the hazards and occupations affected. Further chapters concern the sanitation of factories, industrial fatigue, physical examinations, the conduct of a medical department, questions of compensation, diet, the utilization of the handicapped, and the work of mutual benefit associations. The physician will find no quarrel with this book from the point of view of recommendation of socialized schemes or of tendencies in industries leading to the breaking down of the relationship between the physician and his patient. He will find instead a vast amount of information briefly and succinctly presented by men who have specialized in the field concerned and who write with authority. An extensive index makes the book especially useful to the average reader.

Praktikum der physiologischen Chemie. Teil I. Fermentmethoden. Von Peter Rona. Second edition. Paper. Price, 18.60 marks. Pp. 420, with 107 illustrations. Berlin: Julius Springer, 1931.

This book is devoted solely to ferments and particularly to the ferments found in the animal body. It is especially valuable for workers and investigators in the field of fermentation. Methods of preparation and the determination of activity are treated quite thoroughly. The book has an adequate index. The language is simple, the style clear and direct. The literature quoted is not voluminous but is carefully selected. The volume is divided into two parts, general and special. Under general properties the author discusses preparation, adsorption, elution or the freeing of ferments from combination, dialysis, electrodialysis, conservation, measurement of activity, specificity, influence of temperature and reaction, activating and paralyzing agents. Details of chemical and physical processes and methods are described clearly and accurately, so that the laboratory worker will have little difficulty in carrying out the methods. The special part is devoted to the methods of preparing and studying the action of lipases, esterases, carbohydrate splitting ferments, glycolysis, pepsin, chymosin, trypsin, enterokinase, erepsin, nucleases, amidases and catalases. Each subject is fully treated; for example, two leading methods are given for the preparation of pepsin, and fourteen methods for the estimation of its activity. The description of such physical apparatus as the polariscope, refractometer and colorimeter is complete—perhaps more so than necessary; yet an examination of the book as a whole gives the impression of compactness, completeness, selectiveness and reliability.

Successful Living in This Machine Age. By Edward Albert Filene and Charles Wesley Wood. Cloth. Price, $2.50. Pp. 274. New York: Simon & Schuster, Inc., 1931.

Mr. Edward A. Filene has for years been noted as a public spirited citizen, a successful merchant, and a man who believes that the elementary ideas which make for successful merchandising can be equally applied in other fields. He was instrumental in aiding Lincoln Steffens in the investigation of Boston politics, made many years ago. He has also been a member of the Committee on the Costs of Medical Care since its foundation, and is indeed credited with the idea behind this committee and its work. He himself established the Twentieth Century Foundation, which has aided many important social endeavors.

In his new book, Mr. Filene shows the value of organization for lowering the cost of overhead and for distribution of the expense. Some years ago he contributed to The Journal a paper urging the formation of medical guilds, which were essentially groups, in the belief that group practice would take care of the problem of providing good medical service to all at a price they could afford to pay. In his present book he carries this idea further, but apparently his experience on the Committee on the Costs of Medical Care has made him somewhat doubtful of the certainty that the group is the answer to the problem of medical costs. Mr. Filene writes succinctly, with humor, and his views are interesting.

Studien zur Entwicklung der menschlichen Lungenphthise: II. Phthisische Entwicklungen aus den Reihen des Frühinfiltrates und des frühen phthisischen Nachschubes. Von Hermann Braeuning und Franz Redeker. Nr. 39, Tuberkulose-Bibliothek. Beihefte zur Zeitschrift für Tuberkulose. Herausgegeben von Prof. Dr. Lydia Rabinowitsch. Paper. Price, 22 marks. Pp. 112, with 100 illustrations. Leipzig: Johann Ambrosius Barth, 1931.

The book consists of case reports, serial x-ray films and carefully studied comments on the earliest film signs of focal development in the tuberculous. The work deals at length with the subject of successive infiltrations (Schuebe). An interesting series of roentgenograms demonstrates the progress of the process from the minimal to the grosser lesion. The subject is more easily understood if recourse is had to the first report on it by the same authors. The writers raise the question Can one differentiate between a really new focus and a perifocal inflammatory reaction of an old focus which is buried, so to speak, in an infiltrated area? Arguing the matter, they say that if one accepts the views of Romberg it is easy to recognize that early infiltrations may arise from previously existing small isolated foci. It is quite another thing, say the authors, whether early infiltrations, the term being used in its strictest sense, can be recognized roentgenographically when they are of pin-head size; this presupposes that the disease process is located in hitherto healthy lung. This is an important and practical question. The authors are candid and frank in their statements, acknowledging the difficulty of determining the points at issue. They admit that their long study has not given them incontrovertible and typical examples from which conclusions may be drawn. The work done proves once more the immense value of serial x-ray plating, carefully done and studied. It also shows the value of constant control of tuberculosis workers. Of these, the authors believe, far more become infected than is generally believed. The little work appears to be of unusual importance. It should be checked by competent roentgenologists.

Lane Lectures on Experimental Pharmacology and Medicine. By Rudolf Magnus. Stanford University Publications, University Series, Medical Sciences, Volume II, No. 3. Paper. Price, $1. Pp. 108, with 42 illustrations. Stanford University: Stanford University Press, 1930.

This monograph contains three of the five Lane medical lectures that were to have been delivered in 1927 by the late Professor Magnus. Only these three lectures were completed at the time of the sudden death of Magnus in Pontresina, Switzerland. The three lectures concerned the experimental pathology of the lungs, choline as an intestinal hormone, and the physiologic *a priori*. The last lecture is partly an interesting philosophic dissertation and partly a discussion of Magnus's work on the labyrinth. The first two lectures deal with favorite experimental problems which Magnus and his pupils investigated with great skill. The work on lungs appears to have been stimulated by some experiences of Magnus with poison gases during the World War. The work with choline was suggested by a chance observation of one of his assistants, who showed that a saline solution in which was bathed a piece of intestine acquired the property of stimulating a normal piece of intestine. Studies of this phenomenon ultimately showed the practical usefulness of choline as a remedial measure in intestinal paresis and paralytic ileus. Each lecture has a list of references. Besides the lectures by Magnus, the monograph contains a biographic sketch of Magnus by H. H. Dale of London, a short preface by P. J. Hanzlik of San Francisco, a list of Magnus's works by deKleijn of Utrecht, and an excellent portrait of Magnus. This monograph is in a sense a memorial volume issued by Stanford University in honor of her most illustrious Lane lecturers.

The Official History of the Australian Army Medical Services in the War of 1914-1918. Volume I: Part 1. The Gallipoli Campaign. By Colonel A. G. Butler, D.S.O., V.D., B.A.; Part 2. *The Campaign in Sinai and Palestine.* By Colonel R. M. Downes, C.M.G., V.D., M.D.; Part 3. *The Occupation of German New Guinea.* By Colonel F. A. Maguire, D.S.O., V.D., M.D., and Captain R. W. Cilento, M.D., B.S., D.T.M.& H. Cloth. Price, $5.25. Pp. 873, with 228 illustrations. Melbourne: Australian War Memorial, 1930.

Australia was not responsible for the complete organization of any military force during the World War apart from the expedition to New Guinea. The policy of the Australian medical units was that of the British forces with whom they were associated. This volume is a presentation of the experiences of the Australian Army Medical Service. It is divided into three parts: (1) the Gallipoli Campaign, (2) the Campaign in Sinai and Palestine, and (3) the Occupation of German New Guinea. The administrators of the medical service of the Australian forces were almost without exception civil practitioners who suddenly became responsible for the medical administration of a large military organization. The editor shows the difficult problems that confronted officers who had so little time to prepare for extensive military work. In addition to the Australian records, England made available to the editor records of the British army, which together make the history complete. This and the succeeding volume of the history of Australian medical forces will be unique in that it will show historically the details of a close and successful cooperation between two different medical services. The problems of the Australian medical officers are exhibited in the order in which they arose. The various chapters discuss the evolution of the Australian army medical service, mobilization of the A. I. F.; the first convoy; strategic preparations; the landing at Gaba Tepe; the expeditionary base; disease at Gallipoli; supreme effort: Sari Bair; the disease debacle; the rush of sick; Lemnos; the evacuation; pathology; the service in Australia; defense of the Suez Canal; health in the desert; the first Amman raid in the Palestine campaign; the dash to Damascus; the advance through Syria; the capture of Rabaul.

A Thousand Marriages: A Medical Study of Sex Adjustment. By Robert Latou Dickinson and Lura Beam. Foreword by Havelock Ellis. Medical Aspects of Human Fertility Series. Issued by the National Committee on Maternal Health, Inc. Cloth, Price, $5. Pp. 482, with illustrations. Baltimore: Williams & Wilkins Company, 1931.

The last five years has witnessed a flood of volumes on sex and sex life. Many of the most important contributions have come from American investigators, for instance Dr. Katharine B. Davis, Dr. G. V. Hamilton and Dr. Robert L. Dickinson. The present volume includes an aspect of the subject not covered in previous communications—the physical side. Dr. Dickinson as a gynecologist was concerned not only with mental disturbances but also with the actual physical structure of his patients, which in some instances may have been the responsible factor in marital failure. He is, however, a practical psychologist and has not permitted the physical point of view to obliterate the equally important psychologic considerations. The introduction by Havelock Ellis is philosophical. The Committee on Maternal Health has cooperated in the assembling of the data and the book may be considered a sound contribution to this field.

In the opening section the nature of the study is set forth; then come considerations of the new bride, frigidity, passion and dyspareunia. The third section deals with adjustment, fertility, widows and the necessary normal controls. Then comes the opposite group with the headings maladjustment, fear, substitution and compensation, conflict of education, and separation and divorce. The last two chapters are devoted to passion and frigidity and to a summary of the significant facts brought out by the study. In an appendix there appears an outline for a suitable case history in this field, a proper development of such a case history and a topical analysis of the points of the various chapters.

The book is based on approximately a thousand case histories, which are cited in sufficient detail to teach the lessons they are planned to teach. Space is not available in a book review even to outline the important facts brought out in this volume. Indeed, most of the points are probably familiar to every physician. The consideration is good and the demonstration of the relationship of these physical and sexual factors to successful marriage should be well established in the physician's mind.

Ergebnisse der Kreislaufforschung. Monographien aus dem Gebiete beschreibender, experimenteller und klinischer Kreislaufforschung. Herausgegeben von Dr. Med. Bruno Kisch, ord. Professor der Physiologie an der Universität Köln. Band I: Die reflektorische Selbststeuerung des Kreislaufes. Von Prof. Dr. Med. Eberhard Koch, Abteilungsvorstand am Kerckhoff-Institut in Bad Nauheim. Paper. Price, 18 marks. Pp. 234, with 44 illustrations. Dresden: Theodor Steinkopff, 1931.

This book will prove interesting and profitable reading to the physiologist and clinician interested in cardiovascular problems in health and disease. Many of the older physiologists will find it necessary to change their interpretation of many vascular and cardiac phenomena on the basis of the pressoreceptor reflexes resulting from stimulation of the aortic and carotid sinus nerves (and perhaps others distributed to other larger vessels of the arterial circulation). The reflexes are described in terms of their comparative anatomy, physiology, pathology and pharmacology. The book is well written by one who has added his share to the knowledge of the quantitative aspects of the physiologic responses discussed in the volume. A comprehensive bibliography is appended. The clinician will find the book of practical interest and significance in his daily work.

International Studies on the Relation Between the Private and Official Practice of Medicine with Special Reference to the Prevention of Disease. Volume II: Belgium, France, Italy, Jugo-Slavia, Hungary, Poland and Czecho-Slovakia. Conducted for the Milbank Memorial Fund. By Sir Arthur Newsholme, K.C.B., M.D., F.R.C.P. Cloth. Price, $4. Pp. 249. Baltimore: Williams & Wilkins Company, 1931.

The first volume of the series called "International Studies" dealt with the Netherlands, Scandinavia, Germany, Austria and Switzerland. The present volume is concerned with Belgium, France, Italy, Yugoslavia, Hungary, Poland and Czechoslovakia. The second volume follows the plan of the first. It considers the nature of health administrations in the various countries, the different social organizations involved and the nature of the medical profession, and discusses the uses of insurance to provide good medical care for all. With a background of much experience in this field, Dr. Newsholme is not moved to ecstacy by every social scheme. As a scientist he views what he sees objectively. Any one wishing a world survey of progress in this field and in health management will find in this series of volumes the best assembling of data thus far available. The third volume will concern conditions in England and Wales, Scotland and Ireland, and a final volume will summarize the subject and make suggestions for further progress.

The Prevention of the Diseases Peculiar to Civilization. By Sir W. Arbuthnot Lane, Bart, C.B., Consulting Surgeon to Guy's Hospital and to the Hospital for Sick Children, Great Ormond Street. Paper. Price, 2/-. Pp. 99, with 44 illustrations. London: Faber & Faber, Ltd., 1931.

This volume was first published in 1929 and is now issued in a cheap edition for general use. In the field of public health education, Sir William Arbuthnot Lane has been a pioneer and merits credit for his service notwithstanding his promotion of occasional departures from scientific medicine. The book deals largely with the fundamental laws controlling the operation of the human body and promotes the view that nature's method is best. Of course, one has to interpret nature's method and to realize that modern civilized man lives in conditions that in no way resemble what may be natural conditions. Unfortunately, in his health teachings Sir William Arbuthnot Lane has also concerned himself with the promotion of various proprietary foods in which his health society seems to have some commercial interest and his views must be read, therefore, with the reservations that such a connection naturally invites.

Fundamentals of Health: The Human Organism, Its Development and Conservation. By T. Bruce Kirkpatrick, Associate Professor of Physical Education, Columbia University, and Alfred F. Huettner, Associate Professor of Biology, New York University. Cloth. Price, $3.80. Pp. 576, with 100 illustrations. Boston: Ginn & Company, 1931.

It is quite difficult to arouse interest in the subject of hygiene and health in college people. Textbooks that have previously been used for instruction in these fields have been so devoid of interest that the result of their study has only been the production of apathy and boredom, if not outright hostility. These authors have attempted to include material that would be more interesting to the student, and their book has been planned mostly from this standpoint. They noted that material dealing with heredity, man's biologic background and embryonic development have aroused the greatest interest of the student, and for this reason the first portion of the book is devoted to these subjects. Then follow chapters on foods, nutrition, muscles, respiration, nervous system, sex reproduction, the internal secretions, and public health. The material is clearly presented and is well illustrated. A sensible attitude has been taken toward matters under dispute and the best of authorities are quoted. This volume should establish itself quickly as a valuable textbook for the teaching of health.

Contribuição ao estudo da biologia do "Strongyloides stercoralis." A' margem de um caso raro, provavelmente inédito, de estrongyloidose. Por Heitor Praguer Fróes. These de concurso á cathedra de medicina tropical na Faculdade de Medicina da Bahia. Paper. Pp. 123, with 21 illustrations. Bahia: A Nova Graphica, 1930.

The author has published an extended account of his studies on the larvae of Strongyloides stercoralis discovered in the pericardial fluid and the pleural exudate of a native of Bahia, Brazil. He discusses in successive sections the classification, life cycle, means of infection, and pathologic results of the invasion of the parasite. An important item is his list of the occurrence of such larvae in unusual locations in the body of the host. While the author has been able to contribute little that is new, the account is unusually complete and accurate. It will serve as a most valuable summary of knowledge for all workers desiring such an account in the Portuguese language.

One Hour of Medical History. Compiled by Benjamin Spector, M.D. Boards. Price, $1. Pp. 88, with portraits. Boston: Beacon Press, Inc., 1931.

This volume, prepared by students in Tufts College Medical School, is in the form of a pageant in which students, representing various famous figures in medical history, speak of the work of these noted men. The fact that students of appropriate nationalities were chosen adds to the interest of this unusual item.

Human Heredity. By Erwin Baur, Eugen Fischer and Fritz Lenz. Translated by Eden and Cedar Paul from the third German edition. Cloth. Price, $8. Pp. 734, with 181 illustrations. New York: Macmillan Company, 1931.

This English translation of one of the most authoritative works available in Germany is made from the third German edition, published in 1927. During the course of preparation, revisions and additions were supplied by the authors, so that this new edition may be considered complete and down to date. The book is divided into sections for which the various authors are responsible. The general theory of variation and heredity is discussed by Dr. Baur; racial differences in mankind are discussed by Fischer; the last three sections of the book, developed by Lenz, deal with morbific factors in heredity, methods for the study of human heredity, and the inheritance of intellectual gifts.

More and more consideration is being given in these times to the importance of constitution and heredity for the health, longevity and happiness of mankind. Physicians are fortunate, therefore, in having available such a systematic and sound consideration of the subject. The ability of the translators to interpret correctly and in good English writings originally in German has been demonstrated in many previous volumes for which they have been responsible. This book may be highly recommended to every medical reader who desires to be well grounded on the important relationships of constitution and heredity to the problems of disease. Especially to be recommended is an excellent index, which is an essential portion of this work.

Medicolegal

Weight of Evidence Required to Prove Malpractice

(Matteson v. Thiel (Wash.), 298 P. 333)

Mrs. Matteson was subjected to an abdominal operation in 1915, and two others for the same trouble, one in 1922 and another in 1923. They were all performed by physicians other than the defendant in this case. In June, 1927, the defendant operated on her for the same condition for which the previous operations had been done. After this operation she suffered pain in the lower left abdominal region until June, 1929, when another physician removed a surgeon's needle from the region in which the pain had been. She and her husband thereupon sued the defendant, blaming him for having left the needle in her abdomen.

The plaintiff testified that prior to the operation done by the defendant she had had no pain such as that she suffered after he operated and that she had no such pain after the needle was removed. The needle that was removed was admitted by the defendant to be such a needle as he and other surgeons commonly use in the operation that was performed, but he denied that he had left the needle in his patient's abdomen. The testimony on behalf of the plaintiff tended to show, however, that all needles used and available in the three operations prior to the one performed by the defendant were accounted for, and that not one of them was left in her body. In the course of the trial, on request of the defendant-physician, the court instructed the jury as follows:

> You are instructed that where circumstantial evidence is relied upon to establish a cause of damage or injury, mere circumstances in a case of this kind are not sufficient to establish a case against the defendant, unless they exclude every reasonable hypothesis of other operating surgeons having inadvertently left the needle in the plaintiff. If the circumstances do not exclude such an hypothesis as unreasonable, your verdict must be for the defendant surgeon.

Judgment was rendered in favor of the defendant-physician, and thereupon the plaintiffs moved for a new trial. They based their motion in part on the instruction stated above, which they claimed was erroneous. They convinced the court of its error, and the court in granting a new trial, solely because of having given Instruction No. 6, set forth above, said:

> It, in effect, advises the jury that where circumstantial evidence is relied upon, the plaintiff cannot recover unless the circumstances exclude every reasonable hypothesis of other operating surgeons having, inadvertently, left the needle in the plaintiff, or, in other words, that the circumstantial evidence must prove the case beyond a reasonable doubt. In several other instructions the rule was correctly stated that the burden was upon the plaintiff to prove its case by a preponderance of the evidence. Instruction No. 6 is inconsistent with this rule.

From the order of the trial court granting the plaintiffs' motion for a new trial, the defendant-physician appealed to the Supreme Court of Washington.

In the opinion of the Supreme Court, the remarks of the trial judge set forth above correctly described the situation. The defendant-physician, however, in arguing in support of his appeal, contended that even though Instruction No. 6 was in itself erroneous, the error had been cleared up by other instructions. The Supreme Court, however, regarded the fact that certain of the instructions given by the trial court were correct as insufficient to justify it in reversing the order of the trial court granting a new trial, citing in support of its position previous cases in which the Supreme Court itself had held that where the instructions are irreconcilable and set up for the guidance of the jury contradictory rules, it is impossible for the court to say which instruction the jury followed in arriving at its verdict. The Supreme Court therefore affirmed the order of the trial court granting the plaintiffs' motion for a new trial.

Wills: Presumption as to Testator's Sanity.—In determining the mental status of a testator it will be presumed that he was sane. Where a will appears to be a rational act, performed in a rational manner, this presumption and the apparently rational act amount to evidence of testamentary capacity. The fact that a testator has been adjudged incompetent to manage his property and business affairs and that a guardian had been appointed prior to the date the will was executed is evidence of incompetence which may be overcome by other evidence, showing that the testator was mentally competent at the time of the execution of his will.—*Peace v. Peace (Okla.), 299 P. 451.*

Evidence: Right of an Examining Physician to Express an Opinion Concerning a Wound.—It is the general rule, according to the court of criminal appeals of Texas, that a physician who has testified with respect to his examination of a wound may express an opinion as to its probable cause, nature, effect and consequences.—*Wharton v. State (Texas), 38 S. W. (2d) 72.*

Workmen's Compensation Acts: Jurisdiction over Physicians' Claims.—Under the workmen's compensation act of California, proceedings by a physician or by a hospital before the industrial accident commission to recover the value of services rendered an injured employee are subordinate to proceedings by the employee to recover compensation. They cannot be considered independently by the industrial accident commission.—*Pacific Employers' Ins. Co. v. French (Calif.), 298 P. 23.*

Workmen's Compensation Acts: Liability of Employer for Malpractice of Physician.—An employer furnishing medical aid to an injured employee is bound only to exercise reasonable care in selecting his physician. If he exercises that care, he is not liable for his physician's negligence. Where a physician, properly selected by an employer, ordered that an injured employee be taken by automobile to a hospital some fifty miles away, and prescribed the treatment to be administered on the journey by a layman accompanying the patient, the employer was held to be not liable for the employee's death from loss of blood before reaching his destination.—*Stanley's Adm'r v. Duvin Coal Co. (Ky.), 36 S. W. (2d) 630.*

Evidence: Admissibility of Coroner's Verdict.—The verdict of a coroner may be received in evidence to prove that death occurred, but not to show the cause of death.—*Childers v. National Life and Accident Ins. Co. (Mo.), 37 S. W. (2d) 490.*

Society Proceedings

COMING MEETINGS

Alabama, Medical Association of the State of, Mobile, April 19-22. Dr. D. L. Cannon, 519 Dexter Avenue, Montgomery, Secretary.
American Association for Thoracic Surgery, Ann Arbor, Mich., April 18-20. Dr. Duff S. Allen, 3720 Washington Blvd., St. Louis, Sec'y.
American Association of Anatomists, New York, March 24-26. Dr. George W. Corner, University of Rochester School of Medicine, Rochester, N. Y., Secretary.
American Association of Physical Anthropologists, Washington, D. C., March 21-23. Dr. D. J. Morton, 632 W. 168th St., New York, Sec'y.
American College of Physicians, San Francisco, April 4-8. Mr. E. R. Loveland, 133 South 36th Street, Philadelphia, Executive Secretary.
Arizona State Medical Association, Globe, April 21-23. Dr. D. F. Harbridge, 407 Goodrich Building, Phoenix, Secretary.
Arkansas Medical Society, Little Rock, April 5-7. Dr. William R. Bathurst, 814 Boyle Building, Little Rock, Secretary.
Medical Society of the Missouri Valley, Omaha, Neb., April 5-7. Dr. Joseph D. McCarthy, 107 South 17th Street, Omaha, Secretary.
Mississippi State Medical Association, Jackson, April 12-14. Dr. T. M. Dye, Clarksdale, Secretary.
North Carolina, Medical Society of the State of, Winston-Salem, April 18-20. Dr. L. B. McBrayer, Southern Pines, Secretary.
South Carolina Medical Association, Columbia, April 19-21. Dr. E. A. Hines, Seneca, S. C., Secretary.
Tennessee State Medical Association, Memphis, April 12-14. Dr. H. H. Shoulders, 706 Church Street, Nashville, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Annals of Otol., Rhinol. and Laryngology, St. Louis

40: 987-1306 (Dec.) 1931

*Evaluation of Caloric and Rotation Tests. L. Fisher, Philadelphia. —p. 987.
Osteomyelitis of Skull: Osteogenetic Processes in Repair of Cranial Defects. A. C. Furstenberg, Ann Arbor, Mich.—p. 996.
Rhinosporidium. W. L. Hanson, East St. Louis, Ill.—p. 1013.
Congenital Atresia or Obstruction of Nasal Air Passages. V. P. Blair, St. Louis.—p. 1021.
Scientific Aspects of Work of American Federation of Organizations for the Hard of Hearing. E. P. Fowler, New York.—p. 1036.
Comments on Changes Occurring in Medical Practice: President's Address. C. H. Bowers, Los Angeles.—p. 1049.
Microscopic Observations of Eustachian Tube. Dorothy Wolff, St. Louis. —p. 1055.
Otolaryngologic Aspects of Commercial Aviation. R. A. Fenton, Portland, Ore.—p. 1070.
*Prognostic Significance of Sinusitis in Children. L. Richards, Boston. —p. 1076.
Management of Fractured Nose. E. F. Risdon, Toronto.—p. 1094.
Diagnosis and Conservative Treatment of Sphenoid Suppuration. W. A. Wagner, New Orleans.—p. 1099.
*Mastoiditis in Infants: Review of Literature with Summary of Cases Studied. W. H. Johnston, Santa Barbara, Calif.—p. 1115.
Endotracheal Anesthesia: New Technic. A. E. Guedel, Beverly Hills, Calif., and R. M. Waters, Madison, Wis.—p. 1139.
Acute Generalized Bronchiolectasis with Bullous Emphysema. O. McGillicuddy, Denver.—p. 1146.
Progressive Osteomyelitis of Cranial Bones Secondary to Suppurative Nasal Sinusitis. C. F. Yerger, Chicago.—p. 1164.
Streptothrix Infections of Mastoid, Middle and External Ear. R. C. Martin, San Francisco.—p. 1171.
Decompression of Facial Nerve for Postoperative Facial Paralysis: Two Cases. J. M. Smith, New York.—p. 1179.
Development of Head Lights and Introduction of a New Light. P. Good, Chicago.—p. 1184.

Evaluation of Caloric and Rotation Tests.—Fisher states that in the hands of the most expert examiners the caloric and rotation tests serve to diagnose the causes of vertigo in general, to differentiate between supratentorial and subtentorial lesions in doubtful neurologic cases, and to aid in the localization of intracranial lesions. However, even in the hands of those only moderately expert the test can serve in a most definite manner to ascertain exactly the degree of viability of the labyrinth, to establish or rule out the existence of cerebellopontile angle lesions, and to detect early an actual or threatened intracranial invasion in cases of middle ear suppuration, acute or chronic.

Prognostic Significance of Sinusitis in Children.—According to Richards, sinusitis in children has become during the past ten years a well recognized entity, underlying local nasal symptoms and contributing to systemic disturbances in a relationship formerly never dreamed of. Certain types of sinusitis are amenable to local and, particularly in the acute cases, surgical treatment. Many cases of chronic sinusitis will defy all local measures, whether surgical or medical, and can be relieved only by investigation of the underlying physiologic and biochemical dysfunctions that exist in the individual patient. Allergic disorders will be found to play an important part in this connection. In general, the existence of nasal symptoms will be found to parallel the existence of a pathologic state in the sinus as evidenced by roentgen examination. The author believes that only by study and investigation with every clinical and laboratory facility at hand, principally in a hospital, can adequate study of these conditions be satisfactorily carried out.

Mastoiditis in Infants.—In his paper Johnston includes reports from observers in every section of this country and Europe, and with few exceptions the impression was that the so-called gastro-intestinal-mastoiditis syndrome in infants does exist. The most important objective observations are in the ear drum and canal. The most often recorded are drab or gray drum with loss of normal luster, fulness of Shrapnell's membrane, a sagging of the posterosuperior canal wall and obliteration of normal landmarks; in many cases a well developed suppurative otitis media is found at the first examination. Postauricular changes are most unusual. The author believes that all infants with a severe gastro-intestinal disturbance should have repeated ear examinations by a trained otologist. There is less danger to hearing in postauricular drainage than there is in often repeated myringotomies. No mastoid should be operated on unless there are definite objective manifestations in the middle ear and tympanic membrane. The surgical treatment should be done as rapidly as possible, and nature's attempt at repair should not be hindered by curetting away mucous membrane from the antrum. In view of the anatomic conditions found in the infant's ear—a relatively large eustachian tube, the presence in the nasopharynx of infective material and the position assumed for almost twenty-four hours a day—it is reasonable to deduce that a middle ear and mastoid infection would be the most probable condition produced. Regardless of whether the middle ear and mastoid infection is coincidental with or the etiologic factor in gastro-intestinal disturbances, it is a most important factor in the final outcome of the case.

*Effect of Ingestion of Water and Dextrose Solution on Emptying Time of Normal Stomach. H. H. Kasabach, New York.—p. 1237.

Sympathetic Activity in Certain Diseases.—Scott and Morton call attention to the fact that pioneers have recently opened up important possibilities in the application of anatomic and physiologic knowledge of the sympathetic nervous system to several clinical syndromes. For the achievement of sound progress in this interesting field there is now needed the establishment of criteria by which to measure the sympathetic activity in the various systems. The effect of the temporary interruption of the extrinsic nerve supply to the large bowel by spinal anesthesia is offered as an index of the amount of sympathetic inhibition present in megacolon. For vascular diseases of the extremities, a simple, systematic test is outlined that distinguishes the effects of spasm and of occlusion. The vasoconstrictor stimuli to the area studied are interrupted by anesthesia, the effect of which on the surface temperature is compared with the similar response in normal persons. The authors have established the normal levels for spinal, general and conduction block anesthesia. In an individual case, if anesthesia is not accompanied by elevation of temperature in the cool distal part of the extremity, occlusion without spasm is present; if the skin temperature reaches the normal vasodilatation level, sympathetic vasoconstriction is responsible for the circulatory symptoms, and if the elevation is definite but not to this level, both occlusion and spasm participate. The difference between the highest temperature obtained and the normal vasodilatation level has been termed the occlusion index, as it measures the effect of organic obstruction to the peripheral circulation. Nerve block anesthesia is particularly useful in this vasomotor test on account of its simplicity and its freedom from discomfort. In doubtful or borderline cases its results should be checked with those of spinal or of general anesthesia. By these methods, valuable information in regard to the nature and the treatment of various types of vascular disease in the extremities is obtained. In the purely occlusive group, some compensatory mechanism releases the collateral and terminal vessels from vasoconstriction when the local circulation is seriously reduced. This does not obtain in the spastic group. The treatment for these two groups should be along radically different lines. The principle of treatment for purely occlusive disease is the obtaining of a more peripheral distribution of the reduced amount of blood available, while in spastic disease the treatment should be directed toward an augmentation of the local circulation by overcoming sympathetic vasoconstrictor spasm. Particularly valuable methods are hyperthermia, which produces temporary vasodilatation, sympathetic ganglionectomy for permanent effects, and interruption of the peripheral nerves in cases in which ganglionectomy is desirable but contraindicated by the patient's condition.

Meningococcal Endocarditis.—Gwyn reports the case of a woman who for eight months showed symptoms and physical signs customarily associated with infection of the heart valves by Streptococcus viridans—subacute bacterial endocarditis. Blood cultures in the last two weeks of the illness were positive for meningococci. Death took place as a result of invasion of the brain and spinal cord by the meningococci. The observations at necropsy agreed closely with those described as occurring in association with subacute bacterial endocarditis. Meningococci were recovered at necropsy from the meninges only. The lesions in the heart and kidney as described were apparently in accordance with those observations recorded at necropsy in cases of subacute bacterial endocarditis.

Exercise and Cardiac Infarction.—Sutton and Davis noted that a rest period of six days after infarction resulted in a small, well contracted scar without thinning of the ventricular wall in one dog. In four other dogs, exercise, within three days after operation, resulted in thin scars with aneurysmal bulging. Although there was some variation in the roentgen silhouette from time to time, it was noted that the final average did not show any evidence of hypertrophy or of dilatation. Adhesive pericarditis did not cause hypertrophy.

Amidopyrine in Rheumatic Fever.—According to Schultz, amidopyrine has been used widely as an effective antipyretic and analgesic in a variety of diseases. Excepting the results in typhoid, experience indicates that amidopyrine may be employed in daily doses of at least 3 Gm. without provoking symptoms of toxicity. Instances of idiosyncrasy are less frequent than with many other drugs of this type. In rheumatic fever it has been found effective in patients who are not relieved by other drugs or who are unable to tolerate them in therapeutic doses; and total daily doses of less than 2 Gm. have been found adequate in this disease. The feasibility of giving effective quantities without provoking untoward side actions, as well as the wide margin between therapeutic and toxic doses, renders this drug particularly valuable in the treatment of patients with rheumatic fever.

Brucella Infection.—Leavell and his associates present a case of Brucella infection with fever of seven days' duration. The possible significance of cases of such short duration is discussed, with regard to the possibility that the patients in whom they occur might subsequently become carriers and with regard to the development of cutaneous hypersensitiveness to Brucella and of agglutinins for Brucella antigens. The difficulty of diagnosing such a case by ordinary clinical methods is pointed out.

Contraction and Evacuation of Gallbladder.—Crandall found that sham feeding and direct stimulation of the vagus and splanchnic nerves in dogs, and psychic stimuli and the injection of epinephrine in human beings did not have any effect on the motility of the gallbladder. The gallbladders of dogs, when filled with brominized oil that is less than three times as viscous as bile, spontaneously empty about half of the oil in from eighteen to twenty-four hours. The gallbladders of dogs when filled with iodized oil of the usual relatively high viscosity spontaneously empty about half of the oil in from twelve to twenty-four hours when the resistance of the intramural portion of the common bile duct is eliminated. In fasting human subjects little tendency toward spontaneous emptying of the gallbladder is observed. In human subjects on a carbohydrate diet there is a tendency toward emptying of the gallbladder over a period of from twenty-four to forty-eight hours. It is concluded that the liberation of cholecystokinin by the action of fat or of acid in the intestine is the major factor concerned in the contraction and evacuation of the gallbladder that follow a mixed meal. Duodenal motility facilitates this process.

Postoperative Pneumonia: Prophylaxis.—By the use of a technic which he describes and which he has developed over the past five or six years, Franken believes that the mouth can be put into a reasonably clean, hygienic state before operation is performed. His preliminary report on 859 surgical cases in which definite preoperative oral care was given indicates a measurable drop in postoperative pneumonias. In the figures submitted, this drop amounts to two thirds, and as nothing was changed and no other measures were taken, it seems to point out the practical value of a standard preoperative oral routine. This routine can be established in any general hospital with comparatively small expenditure, but it requires constant cooperation and surveillance.

Emptying Time of Stomach.—The emptying time of the stomach was determined fluoroscopically by Kasabach in fifty healthy young college students after the ingestion of 500 cc. of water and of an equal quantity of 50 per cent dextrose solution containing a very small quantity of barium sulphate, with the subjects sitting or walking about, and in twenty cases with the subjects running continuously, between observations. The total number of experiments on the fifty students was 110. No difference was observed in the rate of emptying of dextrose solution and of water in either group. Exercise (running) seemed to produce a definite acceleration in the emptying time of the stomach. In these experiments, as exercise accelerated the emptying of the stomach it seems justifiable to conclude that dextrose solution in a palatable form could be administered to athletes before a contest in which readily available fuel is required, without fear of producing gastric retention.

Adenocarcinomas of Tonsil and Pharynx.—New and Childrey believe that so-called mixed tumors, which might better be designated adenocarcinomas of mixed tumor type, are not rare in the pharynx or palate. The commonest situation is the palate. Seventy-four cases are reported. The origin of the tumor probably depends on embryonic displacement or enclaves. The tumors are formed of epithelial and connective tissue elements, and the cartilage or mucous tissue in them is not derived from epithelial cells which have differentiated to the extent that they can be recognized as epithelial cells. The tumors may occur at any age but are most common in the fourth decade. Men are affected a little more often than women. The tumors are occasionally discovered in examination of the throat. The average duration of the lesions is 4.58 years. Symptoms and signs that depend on the situation and extent of the tumor are variable and at times unusual. Most common is a sensation of irritation or soreness of the throat. Ordinarily the tumor is single, sessile, firm, circumscribed and movable, with a smooth nonulcerated surface, but variations occur in these features as do variations in size. The average diameter of the tumor when the patient comes for examination is 5 cm. Histologically, the tumor presents a complex structure formed by epithelial elements in varied arrangements on a matrix of cartilage or mucous tissue with which it is characteristically blended. The neoplasms are potentially malignant, for they may contain squamous cell epithelioma and they sometimes metastasize to the cervical lymph nodes. They should be completely removed surgically. Operation may be supplemented by diathermy, cautery or irradiation. Of seventy-four patients seen by the authors over a period of fourteen years, forty-eight were treated. Of these, 56.5 per cent had been treated previously, 32.6 per cent having had surgical treatment. Of the forty-eight patients treated, forty-one (85.5 per cent) were traced. Thirty-nine are alive an average of sixty-eight and a half months after treatment. In the group of thirty-nine living patients there are twenty-nine who have been free from symptoms for four years, fifteen for seven years, eight for nine years and four from eleven to thirteen years. Two patients died of the tumor thirty-five and a half months after examination. Twenty-six patients were not treated. Sixteen of these were traced and seven were found to be alive, but five of them still had tumors. Nine patients are known to be dead. The neoplasm was the cause of death of six of these.

Malignant Tumors of Tonsil and Pharynx.—New and Childrey report 220 malignant tumors of the palate, oropharynx and tonsil. These malignant neoplasms, which are fairly common, consist principally of squamous cell epitheliomas and are almost five times as common as all the other types of malignant tumors, with the exception of so-called mixed tumors. The squamous cell epitheliomas are principally of an active type and have been miscalled lympho-epitheliomas and transitional cell carcinomas. Sarcomas in the pharynx are principally lymphosarcomas, and these comprised 14.55 per cent of the authors' 220 cases. A few fibrosarcomas were seen and a small group of tumors of various types, including hemangio-endothelioma, melano-epithelioma, myeloma and malignant dermoid. The average age of all patients was 54.7 years. Of these, 87.7 per cent were men. The most common situations for malignant pharyngeal tumors are the soft palate and faucial pillars. Except for lymphosarcoma, malignant tumors are rarely primary in the tonsil itself. Extension of the lesions to involve neighboring structures is common, and these include the tonsil, pharynx or hypopharynx, cheek, jaw, alveolus, tongue and floor of the mouth. Metastasis is common; on the patients' admission to the clinic this was apparently present in the cervical lymph nodes in 65 per cent of the cases. Differential diagnosis is important from the prognostic and therapeutic points of view, and the only satisfactory method is by means of microscopic examination of tissue. The prognosis as to length of life, grave in most cases, is better in low grade epithelioma, fibrosarcoma and the few lesions of less active type. The prognosis is affected unfavorably by previous treatment. On 37.7 per cent of the authors' patients, operations had been previously performed elsewhere. Selection of patients for treatment is important; 36.69 per cent of all patients were treated at the clinic. Of the eighty treated patients, twenty-eight (35 per cent) had been operated on elsewhere. Treatment as carried out at the clinic consisted of surgical excision of accessible growths or of destruction of these with cautery or diathermy. Radium in the form of a plaque, in tubes or needles or as radon seeds was used to supplement the foregoing treatment for the primary lesion. The upper deep cervical lymph nodes are removed in all low grade carcinomas of the pharynx and tonsil if the prognosis of the local lesion warrants. The metastasis to the cervical lymph nodes, if from epithelioma graded 4 or from a lymphosarcoma type of growth, is irradiated with radium packs or high voltage roentgen rays, but other metastatic nodes of a less active type of growth are excised; the neck is also irradiated in such cases. Interest in the few cases of miscellaneous malignant neoplasms lies chiefly in their rarity. The results show a surprisingly large number of living patients and of three, five and seven year cures among those who were treated.

Vestibular Response to Rotation.—Ross and his associates found that the duration of nystagmus resulting from rotation was not increased by moderate doses of pilocarpine, nicotine, morphine, camphor, atropine, cocaine, nitrite, sodium bromide, picrotoxin, apomorphine, caffeine or strychnine. The duration of nystagmus resulting from rotation was decreased to a significant amount by a moderate dose of strychnine. The duration of nystagmus resulting from rotation was decreased in possibly significant amounts by sodium bromide, picrotoxin, apomorphine and caffeine. Spinal anesthesia including the body below the neck increased to a marked degree the duration of nystagmus resulting from rotation. The severing of the columns of Goll and Burdach on one side resulted in a difference in the vestibular response of the two sides, that of the side opposite being the greater. The last three observations lead the authors to believe, first, that the spinal cord exerts an inhibitory influence on vestibular reaction; secondly, that this function is located chiefly in the columns of Goll and Burdach, and, thirdly, that the action is exerted after the fibers have crossed.

Adenoidectomy.—Hill calls attention to the fact that while adenoidectomy is a simple procedure it is more difficult to achieve a clean result in that operation than in tonsillectomy. This is due to a tendency to hurry through this part of the combined operation, to the handicap of the bleeding, to dull instruments and to the difficulty of working in a blind space. Visual inspection of the nasopharynx will reveal many tags and remnants and will expedite their removal; it should be employed as a routine measure.

Radical External Operation on Frontal Sinus.—Lillie reports that in the series of 158 consecutive cases in which a radical operation was performed on the frontal sinus, postoperative complication developed in 45. Three deaths occurred, two from meningitis and one from abscess of the brain. The ordinary convalescence of a patient without complication requires seven or eight days in the hospital, and observation afterward for about the same length of time. Complications may or may not affect the ultimate results. The avoidance of complications is, of course, desirable, but there seems to be no way of determining beforehand what complication may follow operation. Thorough removal of diseased tissue is indicated. Whether the Killian operation, or some modification of it, or the Lynch type of operation is employed is determined by the nature of the disease. Skilful technic, careful consideration of the structures involved, and knowledge of the pathologic changes are highly desirable. In general, it may be said that fear of complications need not deter one from operating in cases in which operation is indicated. Good results far outnumber failures.

Fractures of Femur.—Lund has used practically all recognized methods of treatment in cases of fracture of the femur. He has obtained the best results by the use of the Russell traction apparatus. This method depends on a natural and comfortable position of the limb with a minimum of weight whereby the equilibrium of the muscle is restored; with this restoration of muscle tone and position, the fractured ends of the bone will fall into a more or less natural alinement, provided there is no interposed tissue. One must bear in mind that an absolute restoration of anatomic position is not necessary for a good functional result. The author analyzes the results that he has obtained with the Russell traction apparatus and draws the following deductions: 1. The Russell method of traction is the method of choice in treating all types of fractures of the femur from the intertrochanteric to the lower epiphyseal regions. 2. It gives satisfactory position and alinement in all cases, except when muscle is interposed between the fractured ends. 3. It gives a minimum of permanent changes in the joint as compared with other methods. 4. The average period of traction in fractures of the femur is nine weeks, of hospitalization twelve weeks and of temporary disability nine months. 5. The method is inexpensive, easy to apply and comfortable to the patient, and it materially simplifies nursing care.

Thrombophlebitic Edema.—Zimmermann and de Takáts report that ligation of the iliac and femoral veins, alone or in all possible combinations with the contralateral veins, did not produce edema in the lower extremities of dogs. A localized chemical phlebitis and periphlebitis induced with strong irritants, such as 50 per cent sodium salicylate and tincture of iodine, produced a segmental thrombosis but no edema of the limb. Removal of the iliac lymph nodes together with all the retroperitoneal fatty and areolar tissues from the bifurcation of the aorta to Poupart's ligament failed to produce edema of the limb even when the common and internal iliac veins were divided at the same time. In several animals the dissection was repeated to remove any regenerated lymphatics and the collateral veins were ligated, but edema did not develop. From 50 to 70 per cent alcohol injected peripherally into the femoral vein caused extensive venous thrombosis extending into the tributaries and a marked edema lasting from two and a half to three and a half weeks. An emulsion of barium sulphate in gelatin also produced marked edema. Tissue extracts from muscles of the hearts of dogs, the dogs' own serums and finally a concentrated tissue extract, fibrogen, when injected into the femoral vein, caused an extensive venous thrombosis with marked edema. The edema fluid was hemorrhagic and contained comparatively high percentages of protein, indicating injury to the capillary endothelium. If the fibrogen was prevented from forming a clot by the simultaneous injection of heparin, there was no edema. In spite of marked edema, particles of india ink injected into the foot reached the iliac lymph nodes, although delayed by the pressure of the fluid and by the limitation of muscular activity. An obstruction of the peripheral veins over a sufficiently extensive area with a bland, noninflammatory clot produced marked edema, with but little and only secondary involvement of the lymphatics. These results do not confirm the results of recent workers, who emphasize lymphatic obstruction.

Contraction of Cutaneous Grafts.—Davis and Kitlowski state that the only variable factor in cutaneous grafts is the amount of corium with its elastic tissue. In their experience the whole thickness including all the elastic tissue showed the largest amount of shrinkage, which was 43.6 per cent. The half thickness grafts consisting of only a portion of the corium with about half of its elastic tissue showed a shrinkage of 24.86 per cent. The thick Ollier-Thiersch grafts containing only the finest network of elastic tissue of the papillary layer of the corium had a shrinkage of 11.81 per cent. The true Ollier-Thiersch grafts, which contained only the tips of papillae of the corium and no elastic tissue, had a shrinkage that ranged up to 2 per cent, which might well be considered an error of manipulation. If this percentage of error is subtracted from the other three results, the authors feel justified in saying that whole thickness grafts have a shrinkage of 41 per cent, half thickness grafts, 22 per cent, and thick Ollier-Thiersch grafts, 9 per cent, while true Ollier-Thiersch grafts do not have any actual shrinkage.

Pericardial Adhesions.—According to Trout, adherent pericarditis is found in about 4 per cent of routine necropsies. "Acute rheumatic fever" of childhood is the chief etiologic factor, though tubercle bacilli and other organisms are frequently found to be the cause. The condition is far more frequent than it is usually thought to be. Diagnosis is extremely difficult; careful history, physical examination, roentgenograms and electrocardiograms are of great aid. Results of operations justify the plea for more frequent resort to surgical measures in spite of the difficulty of diagnosis. Avulsion of the left phrenic nerve is advocated by the author to supplement the Brauer operation when the trouble is shown to be due to adhesions between the pericardium and the diaphragm. A description of both the Delorme and the Brauer operation is given. A case is reported in which the Delorme operation was done.

Bile Flow into Duodenum.—Puestow describes experiments in which he noted that in the fasting animal with an intact normal gallbladder the orifice of the choledochus was usually closed, the exposed duodenal segment was relatively inactive, and there was almost never flow of bile. The intraductal pressure in the choledochus was found to be from 140 to 170 mm. of bile. The absence of flow of bile was evidently due to a sphincter mechanism at the duodenal end of the choledochus. The tonus of the duodenal musculature apparently was not the sole cause of the sphincter action, and a special sphincter mechanism was suggested. Food stimulated the flow of brown viscid bile. There was usually an initial ooze beginning with the ingestion of food and lasting for from one to three minutes. This was apparently due to psychic or reflex stimulation. A secondary flow began from ten to thirty minutes later and lasted several hours. The bile flowed in brief oozes and spurts, which were frequently related to activity of the exposed duodenum but often occurred independently. Respiration was not a significant factor in the discharge of bile. The exposed segment of bowel became more active and more hyperemic after feeding and reached a maximal degree of peristalsis about half an hour after the ingestion of food. After cholecystectomy, bile continued to flow in the fasting as well as in the nonfasting state. It was lighter in color and less viscid than the bile that flowed after an aminal with an intact normal gallbladder had been fed. Feeding had little effect on the discharge of bile other than to increase the quantity slightly. The orifice of the choledochus was constantly patent. Duodenal activity and its response to feeding were not influenced by cholecystectomy. After removal of the gallbladder, the intraductal pressure in the choledochus of the fasting animal was reduced to from 10 to 20 mm. of bile. Bile salts administered intravenously produced a profuse flow of thin yellow bile. Solutions applied locally to the exposed segment of duodenum occasionally stimulated a slight degree of duodenal activity and rarely were followed by the expulsion of a drop of bile, but generally they did not produce a definite response.

Peptic Ulcers of Duodenum.—Elman and Hartmann observed spontaneous peptic ulcers in six dogs that lost the total pancreatic juice for thirteen or more days and were kept alive and in good condition by careful feeding and the daily intraperitoneal administration of 500 cc. of Ringer's solution. These observations together with those of others point to the importance of the pancreatic juice in protecting the duodenal mucosa, most likely through its control of gastric acidity, by reflux into the stomach. The development of a high gastric acidity in clinical instances of duodenal ulcerations is explained by the diminished reflux of pancreatic juice due to increased pyloric tone. A number of proved cases of duodenal ulcerations were studied, and marked diminution of acid neutralization in the stomach was noted in all. Pylorospasm from whatever cause by diminishing duodenal reflux promotes a high gastric acidity which may be the only factor needed to prevent traumatic, mechanical or other erosions from healing and, indeed, from developing into a peptic ulcer. On the other hand, a pyloric ulcer causes spasm, which in turn promotes hyperacidity leading to a vicious circle and progression of the lesion. Pylorospasm itself is known to develop reflexly from other lesions in the abdomen, thus explaining the not infrequent association of duodenal ulcerations, appendicitis and cholecystitis. Much clinical study has shown that symptoms of pylorospasm and duodenal ulcerations may develop from or be aggravated by psychic factors presumably mediated through the vagus nerve. The importance of the pylorus in the treatment for duodenal ulcerations thus lies, in part at least, in its effect on the control of gastric acidity. Various operations have been designed, in fact, aiming, by removal of part of the muscle, to prevent pylorospasm. Recently, Morton and Archer called attention to cases of hypertrophy of the pylorus in adults on whom the Rammstedt operation was done with complete cure. Further study may show that this simple procedure may be all that is necessary for the relief of early pylorospasm with or without ulcer.

Ovarian Function and Pregnancy.—Rowe makes a comparison between a group of cases of ovarian failure, of which 300 were functional and 30 surgical in origin, and a similar group in normal pregnant women, 77 of whom were studied at intervals of two weeks for approximately the last six lunar months of pregnancy. To these were added twenty-three controls. Biometric observations on the blood, urine, respiratory and carbohydrate metabolism are recorded and compared. In addition, a brief survey is made of the correlations of a long series of important clinical observations common to the two conditions. It is concluded that there is a certain amount of evidence which is consistent with, though it does not define, a lowered level of ovarian endocrine activity during gestation. The weight of the objective evidence completely negatives an ovarian overactivity—if, indeed, there is such a condition. The close parallelism in the pictures produced alike by functional ovarian failure with amenorrhea and early pregnancy is striking and urges caution in the establishment of a diagnosis until sufficient time has elapsed to resolve the major question.

Clinical Use of Suprarenocortical Extract.—The suprarenocortical extract used by Thompson and Whitehead was made according to the directions of Swingle and Pfiffner and was tested clinically on seven patients. Three of these patients had Addison's disease; three had pulmonary tuberculosis with varying degrees of hypo-epinephrinemia, and one was suffering from arthritis deformans. Precautions were taken to rule out any possible psychic factor in the clinical observations. Favorable results were obtained with all three cases of Addison's disease. The improvement observed is thought to be the result of treatment. Instances of remission and spontaneous recovery in earlier cases are cited to show that the very nature of the disease is such as to make positive conclusions impossible at present. Experience with tuberculous patients shows that the use of this extract is beneficial in improving the general condition but is possibly hazardous from the standpoint of the infection itself. The greatest danger seems to lie in administering excessive dosage intravenously and in giving the extract to patients with active tuberculosis which may be aggravated thereby. One patient with arthritis did not experience any ill effects from small subcutaneous injections. Pain was relieved in the inflamed joints and mobility was reestablished in some of those that had been immovable. Small subcutaneous injections of the extract are advised at the beginning of treatment. Some patients appear to be intolerant to desiccated whole suprarenal given orally. Greater clinical benefit can at times be obtained by combining cortical administration with other glandular therapy for which the case may indicate a need.

Pancreatitis and Diabetes Mellitus.—Sweeney reports a case of a moderately severe diabetes which developed in an individual who had a strong diabetic background. The diabetes was undoubtedly precipitated by a subacute pancreatitis. Following surgical relief of the associated jaundice, the diabetes disappeared and the patient has what appears to be fairly normal sugar tolerance.

Postural Hypotension and Addison's Disease.—According to Duggan and Barr, extreme postural hypotension may occur in Addison's disease and may increase the asthenia and aggravate the gastric symptoms. Study of a case which they report indicates that changes in position are accompanied by a tachycardia, in which respect the condition seems to differ from that of idiopathic postural hypotension. In this case, also, there was no evidence of the anhidrosis which has distinguished cases of the idiopathic form.

Efficacy of Rat's Motor Cortex in Delayed Alternation. R. B. Loucks, Minneapolis.—p. 511.

Mechanism of Vision.—Lashley destroyed portions of the cerebral cortex, as nearly as possible symmetrical on the two hemispheres, in a number of rats. In a few cases the visual nuclei of the thalamus or the superior colliculi were destroyed. When the animals had recovered from the operation, they were tested for capacity to distinguish the position, distance and pattern of visual objects, with the following results: 1. Interruption of the optic radiations at their point of emergence from the internal capsule abolishes all capacity to react to visual objects, although the ability to distinguish between light and darkness is retained. 2. Destruction of a small area in the lateral part of the area striata of the cortex abolishes the capacity to distinguish between visual patterns but leaves the capacity to distinguish the position and to some extent the distance of visual objects. Two objects differing in size may be distinguished. but only on the basis of their total luminosity. 3. Partial destruction of the optic radiations or partial destruction of the lateral portions of the striate area leads to some inaccuracy of vision. On the average, acuity is somewhat decreased and the formation of habits based on discrimination of patterns is slowed. There is little indication of a differential fragility of different phases of pattern vision. 4. Lesions in the mesial portions of the striate area, in the supposed visual association area, or in the motor and somesthetic areas do not have any effect on the capacity to distinguish visual patterns or on the rate of formation of the visuomotor habits studied. The formation of visuomotor habits based on the discrimination of rather complex visual patterns probably does not require the establishment of integrations between the striate area and any other specific part of the cerebral cortex.

Bacillus Coli-Like Organism.—Nungester and Anderson describe a series of variants which were produced from a Bacillus coli-like organism isolated from a case of empyema of the gallbladder. These variants differed in form of colony, with colonial structures of the R, S and intermediate types. A mucoid form of colony is also described. Marked difference in the ability of the variants to ferment lactose is noted when such studies are carried out on solid mediums containing lactose and an indicator. This difference is not noted when the tests are carried out in liquid mediums, because the conditions of liquid mediums favor reversion to the lactose-fermenting type. There is no absolute correlation between the form of the colony and the ability to ferment lactose. All variants, except the mucoid, are agglutinated in a high dilution of the agglutinating serum prepared against the parent form. The failure of the mucoid variant to be agglutinated may be attributed to the physical condition of the bacterial suspension. "Reverted" forms of the mucoid variant were agglutinated in a high dilution of the immune serum prepared against the parent form. Change from the lactose-fermenting to the non-lactose-fermenting forms is effected with difficulty. The reverse change is readily brought about. The influence of various conditions of growth on the latter change, such as a solid medium, the hydrogen ion concentration of the medium, the presence of lactose, dextrose or plain broth and irradiation of the organisms, is reported.

Porcine Strains of Brucella Abortus.—Boak and Carpenter report experiments that they performed to determine whether the temperature-time factor more or less universally used for the pasteurization of milk is satisfactory for destroying the most pathogenic strains of Brucella abortus. On the basis of their observations they conclude that the present requirements for the pasteurization of milk (heating at from 142 to 145 F. for from twenty to thirty minutes) are adequate for destroying the most virulent strains of Brucella abortus.

Blood in Infectious Arthritis.—Bernhardt and Hench made eighty blood cultures from twenty patients with chronic infectious arthritis. Although three different methods of cultivation were used (one of them being that published by Cecil, Nicholls and Stainsby) streptococci were not found in any culture. The authors do not consider the results in their series or in the cases covered by their survey as conclusive arguments for or against the theory that the type of chronic arthritis studied is infectious in origin. Although they are inclined to accept the theory that infection is of significance, it is apparent that, with present cultural methods, it is extremely difficult to isolate organisms from the blood of patients suffering from the condition studied, with any uniformity or with any great frequency.

Interstitial Peripheral Neuritis in Experimental Poliomyelitis.—Jordi states that the peripheral nerves in seventeen of twenty monkeys that were infected experimentally by intracerebral and intranasal methods showed a definite interstitial inflammation. The perivascular infiltrations, mostly by round cells, were generally small and inconspicuous and were not numerous. Infiltrations were found as early as twelve hours after the onset of the paralysis. However, in the three animals the nerves of which were free from infiltrations and in a few animals in which not all the extremities were affected, paralysis had existed for less than six days. Infiltrations were present in the nerves of extremities that were not paralyzed. The sciatic nerves of one normal monkey, which were partly cut twelve and four days, respectively, before the animal was killed, showed secondary degeneration but no signs of interstitial inflammation, thus proving that the interstitial neuritis in experimental poliomyelitis is caused by the specific virus. In early stages of poliomyelitis, necrosis of the ganglion cells, both in the spinal cord and in the intervertebral ganglion cells, and not the interstitial inflammation, is the first manifestation of the virus.

Stability of Fluidextract of Ergot.—Smith and Stohlman present the results of a study of some of the factors influencing the stability of the fluidextract of ergot. They noted that storage at elevated temperatures was a potent factor in bringing about deterioration of the physiologically active alkaloids of ergot. Conversely, storage at icebox temperature seems to insure stability for at least eight months. Incubation at 50 C. for fifteen days causes pronounced deterioration of the fluidextract of ergot. The addition of oxidizing substances under these conditions markedly accelerates, while reducing substances considerably retard the rate of deterioration of the physiologically active alkaloids. The authors' observations indicate that decreasing the p_H of the fluidextract of ergot by varying it within the limits of from 5.2 to 2.2 does not favor its stability. Parallel assays by the colorimetric and Broom and Clark methods applied to a series of fluidextracts of ergot subjected to a wide range of deterioration gave no results indicating a degree of discrepancy greater than that which could be accounted for by the combined probable errors of the two methods.

"Avertin" Anesthesia in Experimental Nephritis.—From their observations on normal and nephritic rabbits, Veal and his associates conclude that "avertin" is contraindicated as a general anesthetic in cases of renal disease. Only in those cases in which the kidney function has been found to be normal should it be used as a general anesthetic. The danger of using "avertin" in cases presenting renal damage lies in the fact that the fatal dose closely approaches the anesthetic dose in such cases, leaving no adequate margin of safety between surgical anesthesia and death.

Toxicity Determinations of Mercurochrome-220 Soluble.—Burn and Greville report that the determination of the toxicity of a sample of mercurochrome-220 soluble by intravenous injection into mice and calculation of the average lethal dose gave a different result in one laboratory from that in another, although the details of technic were the same. Examination of four samples in each of two laboratories showed that there was a constant difference between the results obtained. The average lethal dose in one laboratory was regularly from 1.60 to 1.69 times greater than that in the other. This is a large difference to occur between two laboratories in a simple toxicity determination. It follows that the figure for the toxicity of a particular sample of mercurochrome-220 soluble holds good only for the conditions in which the figure is determined, and that in order to obtain figures that are generally applicable, the toxicity of an unknown sample must be stated in terms of some sample arbitrarily selected as a standard of reference.

*Poliomyelitis in Adults: Sixty Cases. Margaret A. Limper, Huldah E. Thelander and E. B. Shaw, San Francisco.—p. 475.

Persistence of Yellow Fever Immunity.—Sixty serums from persons who had had a disease diagnosed as yellow fever from thirty to seventy years previously were tested by Sawyer for their power to protect monkeys against yellow fever virus; forty-five proved to have this protective power. Five of six serums from persons who had had yellow fever seventy-five years before the specimens were obtained protected monkeys, as did also one specimen taken seventy-eight years after the attack. The immunity from yellow fever ordinarily lasts for life and can be demonstrated by protection tests with the patient's serum, using rhesus monkeys or white mice. The persistence of immunity acquired through an attack of yellow fever is not dependent on any subsequent exposure to the bites of infected mosquitoes. There is evidence suggesting that the concentration of antibodies in the serum may in some cases gradually diminish until the antibodies are no longer demonstrable by protection tests with ordinary amounts of the serum; but it does not follow that in such cases the person becomes again infectible.

Artificial Immunity in Albino Rat.—Miller produced artificially an active acquired immunity to a metazoan parasite, Cysticercus fasciolaris, in the albino rat by periodic injections of fresh or powdered worm material. This is the first report of artificial immunity to a cestode parasite and is one of the few instances of artificially produced immunity to a metazoan parasite. In all but a few exceptional cases the cysts developed normally in the control animals and were completely or almost completely inhibited from growing in the immunized animals. Fresh or powdered worm material, usually injected intraperitoneally, was equally effective in producing immunity. The animal used in these experiments, the rat, is a natural host for the parasite.

Poliomyelitis in Adults.—Limper and her associates report that of 268 poliomyelitis cases in San Francisco in the 1930 epidemic 72 (26.8 per cent) were in persons over 16 years of age. A study was made of the case histories of 60 of these adults. Of the 60, only one was over 40 years old and 34 were between 16 and 25 years of age; 33 were males and 27 females. In course, sequelae and mortality rate (27 per cent) the disease was more severe in these adults than in the children affected in the same epidemic. The deaths among adults accounted for 70 per cent of the total epidemic mortality. Serum therapy seemed far less encouraging in the adults than in children, perhaps because of the later diagnosis in the adult cases.

Decompression of Heart: Case. W. A. Hudson, Detroit.—p. 149.

Bronchiectasis. H. Ballon, J. J. Singer and E. A. Graham, St. Louis.—p. 154.

Bronchial Stenosis. L. Eloesser, San Francisco.—p. 194.

Stab Wound of Heart.—Elkin and Phillips report two cases of successful suture of stab wound of the heart. In one patient the wound was in the right ventricle with severance of the descending branch of the left coronary artery. In the other the wound was in the left ventricle and the coronary artery was uninjured. The electrocardiographic observations in both cases were similar to those seen in clinical occlusion of the coronary arteries. In the patient with ligation of the coronary artery, electrocardiographic changes did not appear until thirty-six hours after injury, a fact of clinical importance in differentiating between coronary occlusion and abdominal disease.

Residual Hearing.—Pressman states that, theoretically, the radical mastoid operation should not be detrimental to hearing. In 372 cases of radical mastoidectomy gathered from the literature, 35 per cent of the patients presented improved hearing, 45 per cent further loss of hearing, and 17 per cent no change. Several cases from the literature are described in which radical mastoidectomy resulted in an improvement of hearing amounting to at least 45 sensation units. Four cases are presented, each with bilateral otitis media and of similar duration on the two sides. One ear in each case was treated conservatively and the other by radical mastoidectomy. The poorer hearing ear was selected for operation. The end-result so far as hearing was concerned revealed that in three cases there was no great difference in hearing between one ear and the other. The fourth case, four months convalescent, presented a greater loss in the ear on which operation had been performed, but this relationship existed prior to operation, and no further loss in hearing followed the radical mastoidectomy. Four additional cases are presented, and the hearing level is compared before and after operation. Two of these four cases presented additional loss of hearing after operation, one shows definite improvement, and in the fourth there is no considerable change in either direction. Two similar groups, each of twelve consecutive cases of chronic suppurative otitis media, are compared so far as hearing is concerned. One group had been treated conservatively and the other by radical mastoidectomy. The nonoperative group presented slightly better hearing, but it is pointed out that patients selected for radical mastoidectomy usually suffer a greater hearing loss prior to treatment than those who are treated conservatively. The difference in hearing level is, at any rate, very slight.

Relations of Dental Infections to Maxillary Sinus Disease.—Alfaro believes that many infections of the maxillary sinus are due to frank or to hidden dental disease or to unavoidable dental trauma. A careful transillumination of all the teeth should be a routine procedure with every rhinologist, supplemented by a dental examination in suspicious cases. A careful examination by the dentist should be advised in all cases of maxillary sinusitis that do not respond to treatment in a reasonable length of time. The radical surgical treatment of chronic antrodental pathologic changes should be performed by the dental surgeon and the rhinologist together. A close cooperation at all times with the dental surgeon will decidedly reduce the percentage of failures.

Surgical Aspects of Biliary Tract Disease.—Deaver states that, among the serious possibilities of gallbladder disease, cholangeitis assumes importance because of its tenacious chronicity, a tenacity which is explained by the fact that the lesion of cholangeitis resides deep in the wall of the bile ducts. The symptoms of cholangeitis are those of infection plus certain features related to hepatic function. The mild case presents fever, malaise, anorexia, jaundice at times, and usually an appreciable enlargement of the liver—the same train of symptoms, in fact, as is seen in catarrhal jaundice, stone in the common duct, and hepatitis, so that differentiation is not always possible. Indications for operation depend on the surgeon's experience in estimating the patient's condition, and the degree of disability suffered by the patient. Some mild cases of cholangeitis may subside spontaneously. A similar acute judgment is required in the more severe cases which are characterized by septic temperature, deep jaundice, profuse sweats, anorexia, nausea, vomiting and marked enlargement of the liver. In these, the margin of safe surgery is easily overstepped. The physician acts best who seeks a surgical opinion early in the early case. The infection being interstitial, cure can be obtained only by continuous, prolonged drainage, such as can be obtained only by means of a T-tube in the common duct. The logic of the treatment is the same as that which applies to localized infection elsewhere in the body by the relief of tension and drainage, but with this difference, that such localized infections are usually acute conditions, whereas most of the lesions of the biliary tract are a chronic, low-grade and well established infection which has led to more or less functional derangement. Simple drainage of the gallbladder will not suffice for a cure in these cases. The gallbladder must be removed because the potential power for future trouble lies in the infection retained within its walls. So, removal of the gallbladder and T-tube drainage of the common duct will be required, according to presenting conditions. This applies likewise to involvement of the common duct and to pancreatitis. The author rarely used biliary drainage by cholecystogastrostomy or cholecystoduodenostomy, not only because he considered external drainage more effective but also because the stoma of either type of anastomosis does not remain patent for any length of time if the common duct is not permanently obstructed. Furthermore, the presence of the anastomotic opening may actually favor an ascending infection for the stomach or duodenum into the gallbladder and the upper biliary tract.

New Method of Outlining the Heart, Its Chambers and Great Vessels.—In outlining the borders of the heart, cardiac chambers and great vessels, Fish uses the Ford stethoscope and has found that more accurate results are obtained in outlining the more superficial structures by substituting a piece of rubber tubing for the bell of the stethoscope. The bell of the stethoscope is first placed just below the tip of the xiphoid process and to the right of the midline (point 1). Then, beginning on the lower thoracic wall and percussing from the sides toward the sternum, using a gentle percussion stroke, one hears a definite increase in volume of sound when the percussing finger reaches a point that corresponds to the surface markings of the inferior vena cava. The course of this vessel can be followed to a point beneath the right border of the sternum at the level of the third interspace, at which point the vena cava enters the right auricle. Then, substituting a piece of one-fourth inch rubber tubing for the bell of the stethoscope, and placing the tubing at point 2 (the right border of the sternum at the level of the third interspace), and using a very gentle percussion stroke, one can percuss out two areas that correspond to the right auricle and right ventricle. Owing to greater depth of the ventricle, it is necessary to use a somewhat heavier stroke when one percusses its borders. When the percussion stroke is properly gaged, a very definite increase in the volume of sound is heard as the borders of the cardiac chambers are reached. The tubing of the stethoscope is again substituted for the bell and moved to point 3 (the third interspace just to the left of the sternum). From this point, by the same method used in outlining the borders of the right auricle and ventricle, one can outline the left auricle and ventricle, keeping in mind the fact that a heavier percussion stroke is necessary in outlining a deeper structure than a more superficial one. Without changing the point of contact for the stethoscope, but using the bell instead of the tubing, one may outline the ascending, transverse and descending rami of the arch of the aorta. If the stethoscope bell is then placed at point 4 (below the xiphoid process and just to the left of the midline), the descending aorta may be traced from below upward; and this is found to coincide accurately with the descending limb of the arch as determined from point 3. As that point overlies the interventricular septum, the outer borders of the heart can be outlined by the same technic. The cardiac chambers previously outlined are found to lie within these borders.

Purpura as Complication of Scarlet Fever.—According to Wood-Smith, purpura is a rare complication of scarlet fever. In the cases to which he has been able to refer in the medical literature, the two sexes appear to be equally affected. Children are more commonly affected than adults. The purpura is most probably due to capillary damage caused by the toxin of the streptococcus responsible for scarlet fever. Purpura may occur during the course of any type of scarlet fever, whether mild or severe. The most common time for the purpura to make its appearance is during the third week of the infection. The platelet count, although often decreased, may be normal. All forms of purpura described are manifestations of the same condition in varying degrees of severity. The death rate is high, and in the fulminant type death may occur in forty-eight hours or sooner.

Hair Eating and Pica in Children.—Smith points out that heretofore the treatment of most cases of hair ball which have been diagnosed during life has been surgical. The ileocecal valve presents much greater difficulty to the passage of the foreign body than does the pylorus. In a case reported by the author, the pain and distention did not appear until the mass reached the ileocecal valve. Roentgen examination, in that by this means it may be possible to ascertain the density, size and number of hair balls present in the stomach, is of assistance both in the diagnosis of this condition and in directing treatment. If a foreign body fills the stomach, the only course is obviously to operate. If, however, several smaller balls are present, expectant treatment may be adopted provided surgical help is always available should acute obstruction supervene.

Rational Dosage of Diphtheria Antitoxin. E. Grundy.—p. 1132.

Shock Following Blood Extravasation.—Browne emphasizes the fact that shock can follow blood extravasation, but this is not inevitable. The first step in the production of shock is a fall in blood pressure, and accordingly as the blood pressure falls to lower levels pulse rate and urinary changes become evident. A persistently falling blood pressure, in spite of prophylactic treatment, is of serious import, and efforts should be made in the presence of such readings to localize and remove the blood effusion. Prophylactic treatment is of the utmost importance. By its use otherwise inoperable cases will be rendered safe for operation. In the event of labor not starting after puncture of the membranes, and so forth, plugging the vagina should be performed without delay, provided the blood pressure is approximately 80 mm. of mercury. Below this level, unless marked improvement in the patient is soon noted, classic cesarean section should be performed.

Nasal Element in Spasmodic Asthma.—According to Dundas-Grant, it is obvious that asthma depends on many disease conditions and is in a way rather a symptom than a disease in itself. This may not afford much immediate consolation to the sufferer but it indicates to the practitioner that it must be analyzed and attacked from various sides. If on one side there is failure, an attack may be hopefully made on another, if undue delay is avoided. On the strength of the results he has produced, he urges writers on asthma in textbooks of medicine to place among their foremost instructions that the nasal condition should be thoroughly investigated and judiciously dealt with.

Prognostic Factors in Dementia Paralytica.—Caldwell states that in dementia paralytica pregnancy doubles the chances of remission. Patients below the age of 40 years make the most economically satisfactory remission, although this should not prevent every patient whose physical state will stand it from receiving treatment quite irrespective of age. In England, expansive and manic patients with dementia paralytica give the best prognosis, while depressed and juvenile cases do not respond satisfactorily to treatment. The ability to remember the primary infection and its treatment is of prognostic value, although neither the length of time elapsing before the onset of neurosyphilis nor the pathologic observations are of any value in this respect. Treatment must be thorough and should be supported by a subsidiary course of an organic arsenic compound after the fever.

Rheumatoid Arthritis.—Copeman believes that the best method of dealing with a case of rheumatoid arthritis which fails to respond to ordinary measures is by a combination of blood transfusion and insulin. No harm will result, and in most cases considerable benefit may be expected. The complete procedure is as follows: 1. Search is made for a toxic focus; if one is found, appropriate treatment is given (the bowel should not be forgotten as a "focus"). 2. If this produces no improvement, one should estimate (*a*) the blood sedimentation rate, to see whether a hidden focus of infection is probable, and (*b*) the sugar tolerance curve, in view of future treatment with insulin. 3. The patient is placed in bed, and two blood transfusions of 500 cc. each are given at an interval of eight days, with intensive physical treatment after each. With nervous patients it is often best to refer to the procedure as a blood "injection," rather than as a "transfusion." 4. The patient should be made to get up on the ninth day. It is important to do this (if she is fit enough) before the psychologic effect of the procedure has worn off, particularly with a patient who is almost resigned to being bedridden, as is so often the case. The patient must be keen to help, and her cooperation and interest must be sought if the best results are to be obtained. 5. The patient is put on an insulin regimen and made to weigh herself every day and chart her weight as a curve to stimulate her interest in the method. Most patients will gain about 1 pound in the first week, and after that from 1 to 2 pounds a week in favorable cases. If the patient has been losing weight prior to the institution of this method, a "latent period" of from seven to ten days must be expected before any gain in weight is made. The patient must be cautioned against the expectation of any "miraculous" result but should be told to expect and report gradual improvement in her general and local condition and weight, the effect on the general health and mental outlook generally being the initial signs of permanent improvement.

*Gastrojejunocolic Fistula, with Megalocytic Anemia Simulating Sprue. N. H. Fairley and T. P. Kilner.—p. 1335.
*Protein in Asthma. T. Nelson and A. D. Porter.—p. 1342.
*Variations in Antigen Content of Serum in Disease. A. Q. Wells.—p. 1348.

Gastrojejunocolic Fistula.—Fairley and Kilner report three cases of gastrojejunocolic fistulas presenting a clinical picture simulating sprue. All presented an anemia of megalocytic type. Two were associated with high secretion of hydrochloric acid, and both responded temporarily to liver extract in adequate dosage. Analysis of the feces showed a high fecal fat with adequate splitting. Chemical examination of the blood revealed a lowered total calcium associated with a normal inorganic phosphorus and a low serum bilirubin content. The rôle of malabsorption in a short-circuited small intestine, and the absence of Castle's stimulating factor in the production of the anemia, are discussed.

Protein in Asthma.—According to Nelson and Porter, a small weekly hypodermic dose of simple animal protein in high dilution is an effective agent in preventing allergic spasm. It is difficult to prolong the action of the protein except in mild cases. The authors agree with van Leeuwen that, while skin tests often reveal the allergic condition, they are not of therapeutic value.

Variations in Antigen Content of Serum in Disease.—When Wells titrated the serums from various animals and from man against the appropriate antiserums, he noted that the antigen content of each species was constant. Antiserums against any one serum do not always contain the same antibody. The author suggests that two antihuman serums contained, in one case antialbumin bodies, and in the other antiglobulin bodies. The serum from some nephritic patients differed markedly from normal human serums in their antigen content. The antigen content and the total protein content in the serum of a horse after severe bleeding showed remarkable agreement.

Abdominal Discomfort.—Russell calls attention to the fact that painful as are many of the disturbances within the abdomen it is a matter for surprise how painless are many of the grossest of them. Ascites, for instance, may be and usually is painless, even in extreme degree, though it will give rise to discomfort often described as a sensation of tightness. In fact, its important symptoms are often situated in remoter regions—dyspnea and cardiac embarrassment, for instance, from pushing upward of the diaphragm. But the more rapid the development of fluid the more likely is pain to be present, and any exudation associated with acute peritoneal inflammation gives rise to severe pain. Tuberculous peritonitis in its acute forms or in the localized suppurative variety may be accompanied by severe pain but is sometimes so painless that its presence is ascertained only through the increasing size of the abdomen or during the routine examination of a patient complaining of general signs of ill health. The mere enlargement of an abdominal organ need not cause pain. An enlarged spleen is usually painless, and even an enormous enlargement may cause nothing more than discomfort or a sensation of weight. How little this discomfort may be is shown by the fact that it is very unusual for a patient suffering from myelemia to consult a physician for abdominal discomfort or pain until his spleen has attained a great size, and it is quite common in those cases in which the patient seeks advice for the general symptoms such as anemia or weakness for a great enlargement of the spleen to be discovered which has produced no symptoms whatever. It is quite a different matter, however, when a patch of local peritonitis develops on the surface of the spleen after an infarction, for instance. Similarly, great enlargement of the liver may cause nothing more than a sensation of weight, but one factor that certainly influences sensation is the rapidity with which the enlargement takes place. A liver that has enlarged rapidly from passive distention with blood in cardiac failure or with bile in obstruction of the biliary passages is much more tender than a liver that has enlarged slowly. Malignant growths may give rise to little pain, and cancer of the liver and even of the stomach may proceed to an almost painless end. No one would belittle the pain of cancer, above all of external parts, but internal growths are sometimes very benign as regards pain and produce little more than discomfort.

Vitamin B in Anemia.—Davidson treated a series of cases of primary and secondary anemia with large doses of vitamin B. The evidence produced was definitely against vitamin B being the antianemic factor contained in liver or liver extract. The author discusses the possible value of vitamin B during the remission stage.

Tonsillectomy, Schick Immunity, and Diphtheria Carriers.—Dudley reports that in a semi-isolated community the total carrier rate for diphtheria bacilli among boys who had been operated on for tonsils and adenoids was half that in a control group. There was, however, no significant difference in the carrier rate for toxigenic diphtheria bacilli; tonsillectomy had apparently only lowered the incidence of avirulent infections. The frequency of positive Schick reactions was twice as great in the control as in the tonsillectomized group. Boys in the Schick susceptible subgroup in which the tonsils had been removed were more easily immunized artificially than boys in other Schick susceptible groups. Evidence is brought forward in favor of the view that tonsillectomy does not, in itself, stimulate the production of diphtheria antitoxin but in some way accelerates latent immunization by the diphtheria bacilli of the environment.

Diphtheria Immunity and Tonsillectomy.—Burton and Balmain made an investigation of 682 children who had been Schick tested in relation to the effect of previous tonsillectomy on diphtheria immunity; 27.6 per cent (190 children) had had previous tonsillectomy. They review the relationship of the following factors to the Schick test and previous tonsillectomy: age, proportion of children Schick positive and Schick negative, artificial immunization and family grouping. The results of the inquiry justify the conclusion that previous tonsillectomy has no influence on the production of immunity to diphtheria in children living in a residential nonrural, noncongested area.

Brill's Disease or Pseudotyphus.—According to McGillivray, Brill's disease is a remittent fever lasting about fourteen days. The onset is usually sudden, accompanied often by severe headache, shivering and vomiting. The patient usually takes to bed. Headache is often intense, the temperature is usually from 38.3 to 39.4 C. (101 to 103 F.) for the first week of the disease; during the second week it is a little higher. About the end of the first week the rash appears and the patient feels worse; this is usually the time poorer patients reach the hospital. At this stage the face is red and swollen, the conjunctivae congested, the eyes glistening, and the headache still severe. There is pronounced cough, but little sputum; what there is is very sticky, and generally the appearance is that of an extremely toxic condition. The high temperature continues with daily remissions of about one degree fahrenheit till the twelfth day, when it falls by crisis or rapid lysis to normal by the fourteenth day. The pulse is slow compared with the rise in temperature. The rash is characteristic of the disease; it usually begins toward the end of the first week and has disappeared before the temperature reaches normal. When fully developed, it shows a dark subcuticular mottling with red points, rather as if one took the mottling of measles and superimposed on it the red points of German measles. It mostly occurs on the chest, abdomen, back and limbs, and is often most marked on the back. In most well developed cases of the disease there is some delirium or mild mental wandering at nights. The patient toward the end of the disease appears acutely ill, but on the temperature falling, convalescence is rapidly established. The mortality is usually quoted at 2 per cent. When death occurs it is usually due to lung complications, and on postmortem examination the most noticeable observation is fibrinous pleurisy with consolidation of portions of the lungs.

Thyroid and Sympathetic Nervous System in Exophthalmic Goiter.—In view of his anatomic, etiologic, experimental and clinical studies Daniélopolu asserts that exophthalmic goiter is a disturbance characterized anatomically by a specific lesion of the thyroid, clinically by a series of phenomena related to amphotony. The variations of symptoms (true or abortive Basedow's disease, toxic adenoma of Plummer, para-Basedow's or Basedow-like syndrome) are all variations of the same disease. These different forms are due to the variability of the general sympathetic system, of the cervicothoracic sympathetic chain and of the local tonus of all the organs innervated by the sympathetic system. The thyroid factor and the sympathetic factor work hand in hand and form a vicious circle. The thyroid factor includes a deficiency in the supply of iodine and a disturbance in the iodine metabolism. The thyroid secretion is double: one part passes directly into the blood and another part is stored in the colloids. Amphotony is sympathetic (eyes, heart, blood, vessels) and parasympathetic (digestive system, sweat glands). The author admits the frequency of amphotonic types, the absence of vagotonic types and the infrequency of sympathicotonic types of exophthalmic goiter. Thyroidectomy is more efficient than sympathectomy. Iodine diminishes thyroid hyperplasia and facilitates the accumulation of colloid in exophthalmic goiter; it diminishes the hyperplasia and the colloid in colloid goiter. But the indiscriminate administration of iodine may exaggerate the thyroid secretion and aggravate the disease.

*Routes of Approach to Anterior Mediastinum and Upper Thoracic Cavity. O. Lambret.—p. 613.

Routes of Approach to Anterior Mediastinum and Upper Thoracic Cavity.—Lambret recommends combining the median vertical section of the sternum with section of the clavicle when more room is needed to work in as in posteriorly situated dermoid cysts, or when the posterior part of the thoracic cavity or the pleural dome is involved. Section of the clavicle at the union of its middle and inner thirds renders décollement of the parietal pleura and collapsing of the apex as well as access to the pericardinum an easy procedure. Accessibility may even be increased by allowing the patient's arm to hang vertically over the side of the operating table. The skin incision takes the form of an inverted L with the smaller arm over the clavicle up to its middle third. The sternum is sectioned in the usual way, the clavicle with a Gigli saw, and the sternocleidomastoid muscle is detached with a rongeur. After the sternal section has been lifted, décollement of the pleura is proceeded with and can be done so as wholly to expose the superior thoracic cavity. Drainage is extrapleural and preferably through the axilla. The author describes the different steps of this operation on one of his patients suffering from a dermoid cyst situated in the posterior part of the thorax, behind the pulmonary apex and the great vessels.

Renal Function: Nyiri and Phenolsulphonphthalein Tests. G. Giordanengo.—p. 423.
Access to Terminal Ureter by Raised Inguinopelvic Route. P. Constantinesco.—p. 438.

Genital Tuberculosis of Young Men.—According to Parvulescu and Vascoboinic, genital tuberculosis in young men has as a rule a rapid evolution and the testis is more often involved than is usually stated. Etiologically traumatism should probably be considered on account of the great physical activity natural in young men. Treatment should be conservative and adapted to the lesions found. If surgical treatment is decided on, all scrotal lesions must be extirpated as the principal advantage of surgery in these cases is the rapidity of the cure: consequently this treatment is indicated for patients who cannot afford a protracted medical treatment. Epididymectomy should be performed if the testis is not involved; semicastration is indicated especially in infected fistulous tracts and when the testis is threatened. In case of doubt, ample exploratory orchiotomy is advisable. In bilateral disease, no mutilating treatment is permissible. Spontaneous cures are frequent in young subjects.

*Hepatic Elimination of Tetiothalein Sodium and Its Relation to Cholecystography. M. Chiray, J. Lesage and E. Taschner.—p. 1605.

Hepatic Elimination of Tetiothalein Sodium and Its Relation to Cholecystography.—When Chiray and his co-workers utilized tetiothalein sodium in cholecystography, their study was based primarily on the property of the liver for selective elimination. Although the problem had been studied in animals, the authors believe the studies in man have not been sufficiently controlled. Their aim was to determine a rhythm for the elimination of tetiothalein sodium by the liver and in that way bring about certain improvements in cholecystography. They selected a variety of patients, including some with disturbances in the tonus of the gallbladder, or with dysfunction of the vagosympathetic system and in whom intubation served as an important therapeutic interest from the point of view of the gallbladder. The procedure consists in making comparisons of numerous cases so as to form a standardized curve which would indicate with the greatest possible precision the primary, maximum and final elimination of iodine in the hepatic bile and also the tetiothalein sodium remaining after digestive absorption. Nerve sedatives are given the patient to insure against intestinal spasms during intubation. Altogether four cachets containing 0.8 Gm. of tetiothalein sodium each, with a total dosage of 3.2 Gm., are administered. The cachets are given one after another at different time intervals depending on the conditions of the test. The duodenobiliary drainage, with the collection of A, B and C bile fractions, is performed in the usual manner. The iodine in the bile is calculated by the use of standardized methods. In each test the C bile was collected for half an hour and measured in centimeters; the concentration of iodine per liter of bile was calculated, and the net weight of iodine eliminated in a half hour at various intervals after absorption of the cachets of tetiothalein sodium was determined. This the authors designated as the coefficient of cellular excretion of iodine. The study included twenty-four patients, each examined several times. The elimination of iodine by the liver was noted the third hour after the injection of the dye; the maximum was reached from the tenth to the thirteenth hour and elimination was continued for a variable time with traces present until the fourth to the eighth day. The study of the excretion of iodine in the bile after injection or ingestion of tetiothalein sodium makes possible the study of the physiology of the liver and the gallbladder as well as the mechanism of cholecystography. A negative cholecystographic examination should not always be interpreted as a sign of grave gallbladder disturbance, since one must consider the liver, which assures the elimination of iodine, and modifications of the gallbladder mucosa, which assures the concentration and fixation of iodine.

*"Effort" Thrombophlebitis. C. Lenormant and H. Mondor.—p. 1669.
Epidemic of Chickenpox with Herpes Zoster. P. J. Braslawsky.—p. 1671.

"Effort" Thrombophlebitis.—Lenormant and Mondor recognize that thrombophlebitis may appear spontaneously in normal individuals, who attribute this condition, rightly or wrongly, to traumatism or effort. Many instances are cited in the literature—at least fifty are conditions of traumatic or effort phlebitis of the upper limbs, most often the right upper limb. The authors review two personal *observations*; the first is a clinical history, the second is more complete and convincing since surgical intervention made possible a histobacteriologic examination of the vein and the clot. It is their belief that thrombophlebitis is an infectious disease due to bacteria lodged in the wall of the vein or in the clot; that the influence of effort or traumatism in the appearance of thrombophlebitis is is difficult to prolong the action of the protein except in mild cases. The authors agree with van Leeuwen that, while skin tests often reveal the allergic condition, they are not of therapeutic value.

Variations in Antigen Content of Serum in Disease.—When Wells titrated the serums from various animals and from man against the appropriate antiserums, he noted that the antigen content of each species was constant. Antiserums against any one serum do not always contain the same antibody. The author suggests that two antihuman serums contained, in one case antialbumin bodies, and in the other antiglobulin bodies. The serum from some nephritic patients differed markedly from normal human serums in their antigen content. The antigen content and the total protein content in the serum of a horse after severe bleeding showed remarkable agreement.

Abdominal Discomfort.—Russell calls attention to the fact that painful as are many of the disturbances within the abdomen it is a matter for surprise how painless are many of the grossest of them. Ascites, for instance, may be and usually is painless, even in extreme degree, though it will give rise to discomfort often described as a sensation of tightness. In fact, its important symptoms are often situated in remoter regions—dyspnea and cardiac embarrassment, for instance, from pushing upward of the diaphragm. But the more rapid the development of fluid the more likely is pain to be present, and any exudation associated with acute peritoneal inflammation gives rise to severe pain. Tuberculous peritonitis in its acute forms or in the localized suppurative variety may be accompanied by severe pain but is sometimes so painless that its presence is ascertained only through the increasing size of the abdomen or during the routine examination of a patient complaining of general signs of ill health. The mere enlargement of an abdominal organ need not cause pain. An enlarged spleen is usually painless, and even an enormous enlargement may cause nothing more than discomfort or a sensation of weight. How little this discomfort may be is shown by the fact that it is very unusual for a patient suffering from myelemia to consult a physician for abdominal discomfort or pain until his spleen has attained a great size, and it is quite common in those cases in which the patient seeks advice for the general symptoms such as anemia or weakness for a great enlargement of the spleen to be discovered which has produced no symptoms whatever. It is quite a different matter, however, when a patch of local peritonitis develops on the surface of the spleen after an infarction, for instance. Similarly, great enlargement of the liver may cause nothing more than a sensation of weight, but one factor that certainly influences sensation is the rapidity with which the enlargement takes place. A liver that has enlarged rapidly from passive distention with blood in cardiac failure or with bile in obstruction of the biliary passages is much more tender than a liver that has enlarged slowly. Malignant growths may give rise to little pain, and cancer of the liver and even of the stomach may proceed to an almost painless end. No one would belittle the pain of cancer, above all of external parts, but internal growths are sometimes very benign as regards pain and produce little more than discomfort.

Vitamin B in Anemia.—Davidson treated a series of cases of primary and secondary anemia with large doses of vitamin B. The evidence produced was definitely against vitamin B being the antianemic factor contained in liver or liver extract. The author discusses the possible value of vitamin B during the remission stage.

Tonsillectomy, Schick Immunity, and Diphtheria Carriers.—Dudley reports that in a semi-isolated community the total carrier rate for diphtheria bacilli among boys who had been operated on for tonsils and adenoids was half that in a control group. There was, however, no significant difference in the carrier rate for toxigenic diphtheria bacilli; tonsillectomy had apparently only lowered the incidence of avirulent infections. The frequency of positive Schick reactions was twice as great in the control as in the tonsillectomized group. Boys in the Schick susceptible subgroup in which the tonsils had been removed were more easily immunized artificially than boys in other Schick susceptible groups. Evidence is brought forward in favor of the view that tonsillectomy does not, in itself, stimulate the production of diphtheria antitoxin but in some way accelerates latent immunization by the diphtheria bacilli of the environment.

Diphtheria Immunity and Tonsillectomy.—Burton and Balmain made an investigation of 682 children who had been Schick tested in relation to the effect of previous tonsillectomy on diphtheria immunity; 27.6 per cent (190 children) had had previous tonsillectomy. They review the relationship of the following factors to the Schick test and previous tonsillectomy: age, proportion of children Schick positive and Schick negative, artificial immunization and family grouping. The results of the inquiry justify the conclusion that previous tonsillectomy has no influence on the production of immunity to diphtheria in children living in a residential nonrural, noncongested area.

Brill's Disease or Pseudotyphus.—According to McGillivray, Brill's disease is a remittent fever lasting about fourteen days. The onset is usually sudden, accompanied often by severe headache, shivering and vomiting. The patient usually takes to bed. Headache is often intense, the temperature is usually from 38.3 to 39.4 C. (101 to 103 F.) for the first week of the disease; during the second week it is a little higher. About the end of the first week the rash appears and the patient feels worse; this is usually the time poorer patients reach the hospital. At this stage the face is red and swollen, the conjunctivae congested, the eyes glistening, and the headache still severe. There is pronounced cough, but little sputum; what there is is very sticky, and generally the appearance is that of an extremely toxic condition. The high temperature continues with daily remissions of about one degree fahrenheit till the twelfth day, when it falls by crisis or rapid lysis to normal by the fourteenth day. The pulse is slow compared with the rise in temperature. The rash is characteristic of the disease; it usually begins toward the end of the first week and has disappeared before the temperature reaches normal. When fully developed, it shows a dark subcuticular mottling with red points, rather as if one took the mottling of measles and superimposed on it the red points of German measles. It mostly occurs on the chest, abdomen, back and limbs, and is often most marked on the back. In most well developed cases of the disease there is some delirium or mild mental wandering at nights. The patient toward the end of the disease appears acutely ill, but on the temperature falling, convalescence is rapidly established. The mortality is usually quoted at 2 per cent. When death occurs it is usually due to lung complications, and on postmortem examination the most noticeable observation is fibrinous pleurisy with consolidation of portions of the lungs.
